The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Adult Health: A Legitimate Concern for Developing Countries

Margaret Phillips, MSc, Richard G. A. Feachem, PhD, DSc(Med), Christopher J. L. Murray, MD, DPhil, Mead Over, PhD, and Tord Kjellstrom, MD, MME

ABSTRACT

Adults, defined here as people between 15 and 59 years of age, in developing countries have a high risk of premature death and suffer from frequent morbidity and high rates of chronic impairment. Their ill health imposes a major burden on health services and large negative consequences on families, communities, and societies. This paper describes the level and impact of adult mortality and morbidity, and highlights some of its characteristics and causes, which in some cases contradict commonly held beliefs. It concludes that "adult health" is a legitimate public health concern for developing countries that is not being addressed. An agenda for remedial research and action is proposed. (*Am J Public Health.* 1993;83:1527–1530)

Introduction

In recent years, children have been the principal focus of public health research and policy formulation in developing countries. This attention has been easy to justify, particularly in environments of high infant mortality from preventable causes, and it has led to major advances in the case management and prevention of the communicable diseases of childhood. Nearly 90% of children born in developing countries now survive to be 15 years old owing to substantial reductions in child mortality.[1] However, many of the health problems of adults, including most noncommunicable diseases and injuries, have been neglected.

Adults, defined here as those individuals between 15 and 59 years of age, currently comprise 56% of the total population in developing countries, and this proportion is growing.[2] Adults include most of those in society who are economically productive, biologically reproductive, and responsible for the support of children and elderly dependents. Yet we remain ignorant about the nature and extent of health problems of this group. Adult health in developing countries receives scant attention in public health forums, in journals devoted to epidemiology and health services, and in international policy making. This paper, drawing substantially on work supported by the World Bank,[3] argues that such neglect is inappropriate.

The Level of Adult Ill Health

It is a common misperception that, once the hurdle of childhood is surmounted, the survival disadvantage of living in a developing country is small. Indeed, it is sometimes suggested that adult mortality is higher among the rich. In fact, the risk of a 15-year-old dying before reaching 60 years of age is 25% for men and 22% for women in developing countries, more than double that in the industrialized market economies, where the respective figures are 12% and 5%.[4] In some African countries (e.g. Sierra Leone), the adult mortality risk is more than 50%. Regional estimates of the risk of death between 15 and 60 years of age, together with the risk of death between birth and 5 years of age, are given in Table 1.

Death rates in children are higher than in adults and so, too, is the proportion of child deaths that could be classified as "avoidable" on the basis of comparisons with mortality rates in Japan, the country with the world's highest life expectancy. Nevertheless, more than one quarter of all deaths in developing countries occur in the adult age group, and about three quarters of these 16 million deaths are avoidable. Adults account for about 21% of all

the avoidable years of life lost in developing countries, and for more than that if years are weighted for their productivity and discounted.[4]

The relationship between child and adult mortality is not particularly close: correlating the risk of death between birth and age 5 with that between ages 15 and 60, using data from all populations having recent mortality data, gives a multiple correlation coefficient of .77 for women and of .50 for men.[4] This has two important implications. First, it suggests that modeling adult mortality on patterns of childhood mortality is unlikely to generate accurate estimates. Second, it implies that policymakers cannot necessarily improve adult health by expanding policies that have been effective in controlling childhood illness.

Comparisons with Japan indicate that developing country women have an avoidable excess risk of death between 15 and 59 years of age of 16%, compared with 13% for men; this justifies the special attention given to the health problems of these women.[4] However, total adult mortality risk is actually higher in men than in women in nearly all developing countries and is strikingly so for several southern African countries, a situation that some have attributed to migrant work in South African mines.[5] In Latin America, absolute differences of more than 10 percentage points in the risk of death between ages 15 and 60 between the genders are common. These higher mortality risks in men can even be observed in the reproductive years despite the risks to women associated with childbearing.[4]

Documenting the overall nature of adult morbidity is much more difficult. Although specific disease studies are relatively common (and show high rates in adults for several important diseases), it is not easy to combine these to produce a balanced picture of the burden of morbidity. Household surveys of general morbidity point to high (although highly variable) levels of acute morbidity in developing country adults.[6] In large-scale World Bank surveys in Côte d'Ivoire, Peru, and Ghana, 33% to 45% of adults claimed to have been ill in the past month, with adults accounting for more than 50% of days ill and in the hospital. In Côte d'Ivoire, 20% of all adults claimed to be ill for at least 1 week in the past month, and 7% of them reported being ill for the whole month. Although revealing, these attempts to explore overall morbidity in a single survey also face problems: morbidity can only partly (and expensively) be measured using objective tests, and reliance on self-perceived morbidity introduces a subjectivity that is difficult to interpret. Much of the variation in reported morbidity reflects differences in illness perception and reporting, which may explain the counterintuitive result that reported morbidity is often higher in wealthier communities.[6]

Determinants and Causes of Adult Ill Health

Poverty is clearly associated with adult mortality. Adult mortality risks have been falling over time in most developing countries as overall conditions have improved, and cross-sectional analyses show an inverse relationship between the risk of adult death and gross domestic product per capita.[4] However, the exceptions are provocative. Why have Sri Lankan men, for example, not experienced a decline in mortality in the past 3 decades? Why do some countries (e.g., Costa Rica and Spain) have much lower adult mortality risk than would be predicted by their income, while others (e.g., the Seychelles and the United States) show the opposite?[4]

Some determinants appear to be particularly important in the early stages of development and are closely associated with general conditions in which individuals live.[7] Having a baby is risky in poor countries. Malnutrition and microdeficiency diseases (particularly of vitamin A, iodine, and iron) are important direct causes of some conditions and may indirectly increase susceptibility to many infections. Unhealthy domestic environments are associated with a variety of important communicable diseases, especially diarrhea and pneumonia. Communicable diseases, especially tuberculosis, which causes more than 25% of all preventable adults deaths,[4] explain a substantial part of the mortality differences between developed and developing countries.

These conditions are expected to decline with overall economic development, but this has not been the expectation for many noncommunicable diseases. Many unhealthy behaviors such as tobacco and alcohol consumption are becoming more prevalent with development.[8,9] Development also brings a variety of new environmental hazards.[10] Developing country cities generally have the worst pollution from suspended particulates and sulphur dioxide. Toxic wastes and poorly managed pesticide use are important sources of poisonings in developing countries. Deaths from workplace injuries are about 10 times more common in developing than in developed countries; the risk of dying from injury while working in agriculture in some developing countries is substantial (a risk of death between ages 15 and 60 of 2.4%).[7] Vehicle collisions cause about 0.5 million deaths a year and a similar number of victims with permanent impairment.

In fact, noncommunicable diseases, rather than "tropical" or other communicable diseases, are the leading causes of adult death in developing countries. This is even true in very poor countries like Bangladesh, where the burden of communicable diseases remains high.[11] In those countries possessing adequate data, about 72% of the mortality risk for men between 15 and 59 years (and 82% of that for

women) is from noncommunicable causes, and 23% for men (and 11% for women) is from injuries. Cardiovascular diseases rank first for both men and women, neoplasms rank second for women, and neoplasms and unintentional injuries rank in the top five for men.[4]

Noncommunicable diseases, commonly thought of as diseases of the rich, actually cause higher rates of death in poor countries and among poorer people within a country. For example, a recent study in Brazil shows that groups with lower income and less education have higher mortality rates from cancer, cardiovascular diseases, and other noncommunicable diseases and injuries.[12] Data from China illustrate the same phenomenon (Table 2). Age-specific mortality rates from noncommunicable diseases in general (and cardiovascular diseases in particular) are declining in many developing countries. For the few countries with cause-specific time series data, reductions in noncommunicable diseases explain about 50% of the overall decline in the risk of death between the ages of 15 and 60 for both men and women.[4] In other words, development does not appear to be provoking "epidemics" of noncommunicable disease, although it is true that both the absolute number of cases and the relative importance of these diseases are increasing largely because of the changing age structure of the population.

The failure to observe increases in mortality rates from noncommunicable diseases in adults as countries progress economically remains a puzzle. Westernization and concomitant changes in diet, smoking, and life-style are thought to increase noncommunicable disease rates. The apparently inverse association between the rates of noncommunicable diseases and their putative risk factors might be explained by previously unknown or underestimated etiologies, or perhaps by improvements in medical services postponing death until after 60 years. Some risk factors may be ameliorated by the adoption of protective measures such as pollution controls; occupational safety improvements; and better roads, cars, and drivers. In addition, the lag between unhealthy behavior and subsequent mortality may mean that the negative health consequences are still to come.

TABLE 2—Adult Female Mortality Risk (%) between 15 and 60 Years of Age for Three Groups of Causes of Death in China, 1987 through 1988

Income Quartile	Communicable and Reproductive Diseases	Noncommunicable Diseases	Injuries	Total
I (highest)	0.4	6.7	1.2	8.3
II	0.4	7.9	2.0	10.3
III	0.6	7.6	2.4	10.6
IV (lowest)	1.4	8.9	2.7	13.0

The Impact of Adult Ill Health

Both the relative and absolute importance of adults and their health problems are increasing, despite the fact that age-specific death rates from many diseases (including noncommunicable ones) are falling. The absolute increases arise because of a growing adult population fed by previous or current high fertility. The relative increases are the result of a combination of factors: the aging of the population (with adults forming an increasing percentage of the total population), more rapid declines in exposure to risk factors that affect childhood diseases than to risk factors contributing to adult diseases, and more substantial improvements in therapeutic and preventive strategies for communicable diseases of children than for noncommunicable diseases of adults.[2]

Adults comprise the great majority of the labor force, and it is to be expected that adult ill health would have deleterious effects on productivity. Some studies have indeed demonstrated this.[13–16] In general, however, the evidence is surprisingly weak. There are good reasons to believe that many studies fail to detect productivity effects, not because such effects are not present or not substantial, but because they are obscured or delayed through compensatory reallocations of labor away from other income-generating activities, child care, or education, and that the study designs have not been sophisticated enough to capture these effects[17]: sick workers may do less work at home so as to maintain productivity on the job; family or friends may be drawn from other productive employment to substitute for the ill individual; children may be kept away from school to help; and employers who hire from a sickly work force may build slack into their production schedules and avoid labor specialization.

Illness in adults places considerable demands on health services. Most countries spend at least a half of their health budgets on hospitals, and in countries with data, at least 70% of hospital costs are for adults and the elderly. Adults suffer more from noncommunicable diseases than do younger age groups, and these diseases tend to be expensive to treat. Population-based surveys of medical expenditures reveal that adults spend more on their own health care than on that of other age groups (e.g., 62% of total out-of-pocket medical expenditures in Côte d'Ivoire, according to a World Bank survey.[6]

In the poorest households, ill health of an adult can be catastrophic. Poor adults suffer more often from severe ill health, and are more likely than wealthier ones to depend on regular physical work and to have fewer resources with which to cope. The combination of lost income and the need for major medical expenses in such households can lead to asset sale, debt, and impoverishment. One study in Thailand found that 60% of involuntary land sales were owing to ill health.[18] In Bangladesh, six out of seven households with an ill breadwinner had debts averaging more than four times their monthly income and five times the average level of household indebtedness in that urban slum.[19] Adult illness can even kill other members of the family. Studies in Bangladesh have found that the mortality rates of infants whose mothers die can be as high as 95%,[20] with the death of a mother associated with up to a 10-fold increase in the risk of death in her children.[11]

Countries and communities adopt a wide variety of measures either to cushion the effects of ill health, should it happen, or to reduce the chances of getting ill.[17] Informal insurance mechanisms include alliances through marriage, reciprocal financial transfers that may never be recouped, and savings in relatively liquid forms (which may reduce the scope and hence productivity of investments). Both formal and informal insurance mechanisms are imperfect and involve costs that would not be incurred if individuals knew they were highly unlikely to get ill.

Implications for Research and Action

One response to data showing that adults in developing countries suffer from

serious health problems is to spend more on improving adult health. Since much of the current investment in adult health is inequitable or inefficient, more of the same is not desirable. However, some interventions to improve adult health have not received the attention they deserve, given the substantial health returns they promise per dollar invested.[21] These include certain preventive strategies (notably, to reduce smoking; to promote safer travel, sex, and motherhood; and to reduce liver cancer through vaccination) as well as improved case management (particularly of tuberculosis and diabetes), screening against cervical cancer, and pain relief for cancer patients.

Just how appropriate particular investments will be for any given country depends on many factors, including the epidemiological context and the technical, economic, and political environment in which health policies are implemented. It is unlikely that shifting resources away from children to adults, or from communicable to chronic diseases, can be justified on efficiency or equity grounds; some of the best investments are still in the control of childhood communicable diseases.[21] However, many countries devote substantial public resources to costly and marginally effective treatments of adult diseases, and governments should explore realistic options for withdrawing public funding from such services.

More information is needed on adult mortality and morbidity in the poorest countries, particularly those in sub-Saharan Africa and South Asia. The consequences of adult ill health also deserve closer study. Basic research in developing countries on the pathology of diseases or on the nature of associations between adult diseases and their risk factors is difficult to justify in most cases. What developing countries do need are data on the levels and determinants of exposure to major risk factors so that interventions can be appropriately designed and targeted.[7] Finally, a large body of research remains to be done on the cost-effectiveness of curative and preventive interventions against adult diseases.

Because of ignorance concerning the nature of adult ill health and the cost-effectiveness of potential interventions, policy development in the area of adult health is weak.[22] There are no adult equivalents to the well-researched, thoughtfully developed, and enthusiastically promoted child health programs. The political pressures to respond to the health problems of adults will continue. Governments need the courage and the facts to redirect expenditures into more cost-effective treatment or prevention. "Adult health" must be firmly on the agenda of developing country health policymakers and researchers. □

A Developing Country's University Oriented toward Strengthening Health Systems: Challenges and Results

John H. Bryant, MD, David R. Marsh, MD, MPH, Kausar S. Khan, MA, Rennie D'Souza, MBBS, MSc, Khatidja Husein, MSc, Asif Aslam, MBBS, MPH, Asma F. Qureshi, MBBS, FCPS, Vincent deWit, MBBS, MSc, and Ruth M. Hamar, RN, DrED

ABSTRACT

Objectives. The Aga Khan University in Karachi has a mission to educate leaders and to contribute to the development of health systems for Pakistan amid challenges of scarcity and complexity.

Methods. Its key activities are (1) to design and test urban and rural health system prototypes, (2) to develop faculty in medical and nursing postgraduate community health sciences programs, and (3) to design and implement community-based undergraduate medical and nursing curricula.

Results. The university has developed equity-based, cost-effective primary health care prototypes in Karachi slums. With government counterparts it has tested village-, facility-, and district-level interventions in a poor rural district. Federal policymakers have taken models from each for widespread replication. The university is training 49 medical and 19 nursing faculty for postgraduate programs in community health sciences. Most faculty retain institutional leadership positions, including teaching community-based, problem-solving, community health sciences as 20% of the medical and nursing undergraduate curriculum.

Conclusions. The mission and experience of the Aga Khan University in population-based health systems design and health sciences education can guide universities in both developing and developed countries. (*Am J Public Health.* 1993;83:1537–1543)

The Aga Khan University: Challenges, Mission, Objectives

A university in a developing country faces a particularly daunting task as it seeks development amid pervasive underdevelopment. The familiar landscape is a web of scarcity and complexity, the most obvious components of which are widespread ill health; unchecked population growth; and inequitably distributed, largely ineffective health services. Present mortality and morbidity are likely to remain high, given demographic trends and the context of political instability, economic stagnation, inappropriate technology, and value transfers, all of which exist against a backdrop of habitual disregard for or exploitation of the poor.

The Aga Khan University is the first private university in Pakistan. Because it is 10 years old, its facilities, faculty, research capacity, and institutional maturity seem a limited match for the country's formidable problems. This tension between calling and capacity leads to an inquiry into the university's role.[1] Should it venture into society, risking failure and even its stability? Or should it remain cloistered, risking relevance and missed opportunity? Grappling with these issues, the health sciences faculty has advocated concerted interaction with communities, government, and the health system,[2] both public and private. This role is thus reflected in the university's mission statement:

> The Aga Khan University Medical Center is dedicated to providing exemplary education, research and service, oriented toward finding and disseminating innovations to improve the health of the people of Pakistan and the developing world. (Report of the Aga Khan University Medical Center Committee of the Board of Trustees, March 1993.)

The Department of Community Health Sciences has two main objectives: (1) to strengthen the development of health systems in Pakistan through education and research, with emphasis on the development and implementation of health system prototypes in collaboration with local and national authorities; and (2) to educate health personnel for leadership in dealing with health and development problems, particularly those of the more deprived communities of Pakistan. To what extent has the university accomplished these goals? How generalizable are the findings? Enough has now been learned to justify a report on the university's experience in developing health systems and in educating health personnel. The following analysis examines the problems that were addressed, the university's programmatic response, the results to date, and a commentary.

Health System Development

The university has pursued the development of health system prototypes in both urban and rural settings. Each setting has been uniquely challenging; both have been essential for progress toward health.

The University's Urban Primary Health Care Program

The problem: Given the extensive needs of urban populations living in extreme poverty, coupled with serious inadequacies of governmental health services, is it possible for the university to develop prototypes of urban primary health care[3,4] systems that are effective, affordable, and amenable to large-scale replication?

Karachi is a rapidly growing, sharply changing city with a population that approaches 10 million. The millions of underprivileged people pose a chronic crisis, a "paradox of development that perpetuates underdevelopment."[5,6] Large portions of the burgeoning populations coalesce into

TABLE 1—Selected Baseline Health and Demographic Indicators: Aga Khan University's Urban Primary Health Care Prototypes[a]

Indicator	Group A[b] Prototypes						Group B[b] Prototypes	
	Orangi	Chanesar Goth	Grax	Essa Nagri	Azam Basti	All Five Sites	Baba Island	Karimabad
Infant mortality rate	110	121	170	144	93	126	210	33
Under 5 yrs of age mortality rate	130	171	224	230	111	177	NA	NA
Crude birth rate	41	41	44	44	41	41	39	16
Crude death rate	10	11	16	16	11	10	20	56
Contraceptive prevalence rate	NA	7	6	12	15	...	13	56

Notes. NA = not available.
[a]Baseline surveys were carried out at one to two sites yearly, 1985 to 1988.
[b]Group A = University-led prototypes (more complete data); group B = community-led prototypes.

katchi abadis, slums characterized by poverty, lack of education, contamination, political instability, ethnic violence, and drug running. In the urban setting, government services are fragmented, skewed toward large hospitals, and unable to meet the needs of the poor.

Thus, the university has developed health system prototypes: small, community-based systems that are amenable to study, adaptation, and ultimately large-scale replication. It has seven such modules scattered in Karachi. Six are located in the katchi abadis, each serving a community of about 10 000. Baseline socioeconomic, health, and demographic surveys of these prototypes (Table 1) show high crude birth rates, high infant mortality rates, and high prevalences of infectious diseases and malnutrition (the impact indicators), along with low incomes, overcrowding, illiteracy, and lack of civic amenities.

The seventh site, Karimabad, is a lower-middle-income area. Its lower birth and infant mortality rates, higher contraceptive prevalence rates, and disease patterns similar to those of industrialized countries attest to its progress through the demographic and epidemiological transition.[6] We have coined the term *child mortality burden*[7] as an indicator of the health transition; it is defined by the percentage of total annual mortality affecting children under age 5. In the slums this figure exceeds 50%; in Karimabad it is 18%.

The response: The university has taken three approaches to primary health care in these urban settings: a university-led, a community-led, and a joint health promotion/disease prevention program.

• The university-led model. Five of the urban modules (Table 1, group A) follow the university design of community-based programs, incorporating the World Health Organization's principles of health for all: universal coverage, care according to need, and community participation. This health care system has three tiers of health personnel. At its base are community health workers: women recruited from and trained in the community. These workers are supported by paramedical lady health visitors, who are supervised by a community health nurse and a community health doctor.

The community health workers are the key to equity and coverage, as each worker monitors approximately 125 households, visiting each household monthly. Those people who are ill or at risk are given priority attention. These workers emphasize immunizations, growth monitoring, oral rehydration therapy, and early recognition of acute lower respiratory infections among children; additionally, they identify high-risk pregnant women and advise on family planning.

Simple curative services are available in small health centers. Community participation is encouraged in the programs, as are other health-related activities like income generation, education, and pressing for adequate supplies of clean water and sanitation. To track coverage, effectiveness, and costs of the program, a management information system uses the community health workers' data. Nurses review and aggregate the data; feed it back to the primary health care team; and forward it to the university for computerization, further analysis, and feedback.

• The community-managed model. The model on Baba Island (Table 1, group B), home to fishermen and their families in Karachi harbor, differs from the university-led model. A strong local nongovernmental organization, the Fishermen's Welfare Association, stimulated the community to want to understand the causes for its ill health. Since the decision making was shared between the university and the community, health system development evolved more slowly than in the university-led model.

• The health promotion/disease prevention model. The Karimabad health promotion/disease prevention program (Table 1, group B) enlists community volunteers and private medical personnel as agents for early identification of risk groups, improved health and disease awareness, changed attitudes and practices, and improved management of "posttransition" diseases.

The university-led urban programs have demonstrated improvements in coverage and impact indicators. The infant mortality rate has fallen from 126 to 64; the under-5 mortality rate, from 177 to 83; and the 1- to 4- mortality rate, from 51 to 19 (Table 2).

In 1991, annual costs of these university-led systems averaged US $3.12 per person in the population, or US $12 per woman of childbearing age and child under 5. Backup, off-site managerial costs increased the per capita cost to US $4.00 (Table 3). Table 4 shows the cost allocation to individual components, including curative care, 39.5%; child nutrition, 20.4%; and immunizations, 16.6%.

Although these communities have had gratifying reductions in the infant and young child mortality rates at affordable costs, these quasi-experiments have had no comparison populations in which health status was monitored without interventions. Thus, additional qualitatively comparable katchi abadis communities are being studied to clarify secular trend questions. Nevertheless, on the basis of these prototypes, the government of Sindh Province has asked the Aga Khan University to assist in developing a large-scale urban health care system, financed by the government and the World Bank.

The University's Program for Rural Health System Development

The problem: Given the extreme problems of underdevelopment in impoverished rural settings and an inadequate health system, is it feasible for a university to help strengthen the governmental health system?

Collaborating with the government to improve health in rural settings is a great challenge. Poverty, inequity, insecurity, women's seclusion, and a woefully inadequate infrastructure for communication, transportation, and education make rural primary health care a task well beyond the capabilities of traditional health interventions.

The government has built a substantial health services infrastructure, but this is beset by deep-seated problems of finance, vision, management, accountability, program content, and staffing. For example, there are few female health staff members, a critical problem in this society. Services are marginally acceptable because of drug shortages and the uneven quality of care; this, in turn, has resulted in their paradoxical underuse by an underserved, unhealthy population. Despite a dismal infant mortality rate of 172, health services use is as low as 0.2 visits per person per year.

The response: The university has worked with the government to advance its capacity for conceptualizing, staffing, and managing the system, including reaching communities with primary health care. This was a top priority because a university-led rural prototype developed independently of the government would have little relevance for sustainability or large-scale replication. The preimplementation phase has been qualitative, emphasizing relation building, method testing, and system strengthening. The follow-on implementation phase, now under way, will test and quantitatively monitor interventions undertaken jointly with the government.

Our health systems research project in Thatta District (population of about 1 million), designed in collaboration with the government of Sindh Province to strengthen the health care system, explores interventions at three levels: district, facility with catchment population, and village. These three levels of approach are being compared in their capacities to improve health status. The district level focuses on strengthening district health management, especially management information systems, and on developing female health personnel. Facility-level interventions include center- and community-based primary health care services and a first referral-level hospital. The village focus is to improve health through schools and to enhance village self-development ability.

The outcomes to date include (1) a better understanding of the sociopolitical context of government personnel and rural communities, (2) a modification of the training and system design consistent with extreme underdevelopment and political instability, (3) improved governmental and community capacities, and, importantly, (4) changed governmental attitudes. Less prone to hopelessly lament their limited resources, doctor-managers now consider using such resources more efficiently. The university's capacity and educational programs have also grown. Junior faculty have learned operations research firsthand. Medical and nursing students who might rarely leave Karachi have experienced the challenges of meeting health needs amid rural poverty. Specific programmatic achievements are as follows.

• At the district level, The District Health Management Team evolved over 2 years, through a series of phases, from the districtwide management training component (see Appendix A). By recognizing and encouraging the early interest of participants, the university enhanced these participants' confidence and leadership capacity. The initial training in management encompassed both technical issues and more abstract topics, such as concept development, communication, and community involvement. Indeed, using these

ideas, the trainees became part of the evolving management team, which is now a model of participatory health system problem solving for the province.

Female health personnel have received special training, encouragement, and security assurance. Their knowledge as measured by pre- and posttests has improved, and use of their services has increased. In another initiative, 112 village health volunteers from the catchment area of 20 facilities were trained in basic health activities. Unfortunately, because of inadequate supervision, only 18% remained active after 1 year. But although the program could not be sustained in this form, the government has endorsed its value by seeking outside funding to strengthen it. A major achievement is the university's contribution to the Health Management Information System, which spans the facility and the district and has been accepted for national use.

- At the facility level. In the catchment areas of two facilities, 35 villagers received basic primary health care training. After 2 years with minimal support, 50% of these villagers remain active, and they are enthusiastic about their new capacity for contributing to socioeconomic progress. In another example, usage rates for facility-based antenatal care have increased by 64%. This care is accepted if female staff are reliably available, a crucial strategy to reduce the estimated maternal mortality rate of 1%.
- At the village level. Despite a rural educational system that is even weaker than the health care system, a pilot program has trained 12 teachers in interactive teaching methods. In turn, these teachers have designed and taught modules of six health promotion lesson plans to eager children. Village development workshops have encouraged rural women to identify their own problems, formulate solutions, and take collective action. Because of the lengthy preparatory work required in a setting of feudal inertia, the effects of these workshops at the geographic periphery have thus far been confined to promotion of some health activities and enhanced awareness and organization of certain social groups.

Overall, a strengthened health system is emerging that can initiate and track interventions. Although quantitative evidence for effective, affordable, lasting change awaits further experience, the process has been noted by policymakers. The Thatta project has become the prototype for the government of Pakistan's World Bank–supported Family Health Project, which will serve the 18 million people in every rural district of Sindh Province.

Training and Education for National Health Development

Our programs for human resource development address postgraduates and undergraduates.

Faculty Development: The Aga Khan University Scholars in Community Health Sciences

The problem: Symptomatic of underdevelopment is a scarcity of skilled manpower in community health. How can the Department of Community Health Sciences train leaders in community health and health system development?

The response: The strategy to accomplish this ambitious goal is the Aga Khan University Scholars faculty development track. Now in its ninth year, the program began with a handful of senior faculty and some young Pakistani health professionals. These initial instructor trainees entered a long-term career development track at the completion of which was an uncertain job market. The training they undergo and the wide-ranging jobs these instructors are trained for are described below.

- Community health doctors. Upon entering the program, each physician attends a 6-week "mini–master's degree in public health" orientation to community health. Then, as community health doctors, they join either a rural or an urban field team; as instructors, they teach classroom and field tutorials in the medical college and attend weekly seminars that anticipate teaching responsibilities.

After 3 years of increasing responsibility in the classroom, field, and department, the average instructor has served as a team director and a tutor while developing areas of research and clinical interest. Those recognized as having outstanding research or teaching potential are designated as Aga Khan University Scholars, invited to remain as department faculty, and supported to get a master's degree in their fourth year. Others with different talents needed in Pakistan, such as skills in health system development, primary health care technology, and field work, are assisted in career planning.

Upon their return from master's degree studies, senior instructors assume larger responsibilities in teaching, mentoring, health system development, and research. Many young faculty fill key roles in program development. Years 5 to 7 are spent perfecting skills and defining areas of interest as each instructor plans for doctoral studies and further career development.

- Community health nurses. The community health nurse scholar career development track is smaller, newer, and equally important. Because the nursing profession in Pakistan has long been scorned as unsuitable for young, single Muslim girls, the challenge is both to train nursing leaders[6] and role models *and* to change entrenched attitudes.

Community health nurses join the department after 3 years of diploma nursing and 1 year of midwifery training. As field team members, each works in service, teaching, and management. After 2 years, the nurse enters the 2-year bachelor of science in nursing program. She then works for 2 years refining skills in management, teaching, or field supervision, after which she may apply for master's studies.

To date, the programs are training 49 physician leaders and 19 nurse leaders, numbers that are increasing annually. The faculty development program has a good retention record: more than 45 doctors and nurses are currently in this program, some for as long as 9 years.

The faculty trainees have been monitored rigorously, both internally and externally. Prior to being selected as university scholar in the third year, each trainee receives a series of exacting annual appraisals—qualitative and quantitative evaluations by self, peers, and seniors. Focused, accountable correctives are instituted for lagging performance while acceptable progress is rewarded with new responsibilities. The validity of the internal evaluations is confirmed by virtually every scholar who has excelled in competitive master's programs (such as Harvard, Johns Hopkins, and London). Some scholars have earned degrees with distinction and prizes for scholarship.

The quality of these emerging professionals is confirmed by the array of career opportunities that lie open to them. Nongovernmental organizations and the government have sought consultancies and short-term placements. However, as a gratifying indicator of the scholars' views of this career development track, only 2 of 31 have left the program. Yet, they, too, have assumed important positions in health and development in Pakistan, and the department seeks honorary designations for them. In sum, these young fac-

ulty are the key to the university's innovations in community-based, health system-oriented medical and nursing education, as well as in health system development.

Finally, the instructor/scholar sequence is expensive, averaging US $20 000 per year abroad. The need for an in-country graduate program is obvious. Additionally, the department envisions shorter certificate courses to help educate government and nongovernmental organization personnel who are already committed to working in Pakistan.

Medical and Nursing Undergraduate Education: A Community-Based Approach

The problem: Community health has been accorded low priority and little respect in Pakistan's medical and nursing education. Is it feasible for the university to train its own doctors and nurses for leadership in this field? Can it influence other universities' programs or national health education policy?

The response: Medical and nursing education benefits from the interaction between faculty and health system development. Population-based prototypes serve multiple purposes: they are vehicles for the health and development of deprived populations, training sites for faculty, and settings for students to learn the attitudes and activities of community health from the first month of their medical and nursing careers. Because much of the work is unique and uncharted, communities, students, and young faculty learn as they solve problems together.

• Community health sciences in the medical curriculum. The 20% of the curriculum devoted to community health allows for student learning in socially sensitive and methodologically sound ways that are problem oriented, student centered, competency based, and community based. The 5-year teaching-learning sequence follows a problem-solving process known as the community health planning cycle: community assessment, problem identification and prioritization, vertical and then integrated planning, implementation, and evaluation (Appendix B).

The curriculum is divided into preclinical and clinical phases, 2.5 years in each. Community health sciences are taught through each of the 6 preclinical terms: 2 hours per week in lectures and 5 hours per week in small group tutorials or fieldwork (Appendix B). During the clinical years, quantitative skills are applied to carry out small research projects or health system evaluations. Likewise, clinical skills, taught jointly with the Departments of Pediatrics, Obstetrics/Gynecology, Family Medicine, and Community Health Sciences, are learned through clerkships at several field sites.

Each added field site is unique, as successive classes have learned through community assessments, interventions, and studies. Students benefit from the studies of these field sites. A group of 5th-year students tactfully pretested quality assurance instruments; another group analyzed the potential for using prototypes for large-scale, sustainable replication.

• Community health in the nursing curriculum. The Aga Khan University School of Nursing is unique in Pakistan in that it designates 15% of its diploma curriculum to community health. Educational opportunities for nurses expanded with the 1988 introduction of a two-year postbasic bachelor of science in nursing degree program. Offering the only university degree available for nurses in the country, this program devotes 26% of its curriculum to community health covering fields such as management, education, research, and surveillance. Moreover, the School of Nursing has advised the Pakistan Nursing Council regarding the content of the national community health nursing curriculum and has trained the first tutors.

The undergraduate programs in medicine and nursing can be assessed in terms of the graduates' acquired knowledge, attitudes, skills, and career choices. While educationists grapple with methods to assess the quality of medical curricula,[9] our graduates have a strong foundation in basic, clinical, and community health sciences for addressing the health needs of Pakistan. Desiring to compare their academic performance to an international standard, the first graduating class of medical students asked to take the Canadian Comprehensive Examination. They performed, on average, slightly better than their North American peers (S. C. Robinson, personal communication, 1992).

How the graduates will use their community health experience is less clear. Only five classes of medical students have graduated, and most of those students have opted for postgraduate studies in the United States or United Kingdom. Most speak of returning to confront Pakistan's health problems. Some talk of community health; more imagine a dual focus of a clinical specialty linked with community health, such as community pediatrics. Our medical graduates, like those elsewhere, face multiple factors influencing their career choices: personal and family values, uncertainty of career opportunities, faculty role models, economic considerations, and national need.

Similar comments apply to nursing, which also offers a strong undergraduate program in community health nursing, followed by an uncertain process for graduates sorting out further training needs, career options, and family decisions.

The contrasting commitment between the undergraduate and postgraduate programs no doubt relates to differing selection criteria, professional commitments, and evolving career opportunities. Tracking our graduates' career plans and choices continues.

One strategy for achieving the university's mission in medical education reaches beyond the institution to collaboration with other universities in health and development. For example, the 1993 Workshop on National Priorities in Health Sciences Education called for major nationwide curriculum changes toward population-based orientation, and the Pakistan Medical and Dental Council is asking the university to help develop the implementation strategies.

Conclusions

The Aga Khan University, a university in a developing country, is addressing the problems of severe underdevelopment in the health sector through health system development and education for leadership in the field. In each case, we have defined the dominant problem, reviewed our programmatic response, and analyzed the effectiveness of the results. In several instances, the university's work on prototypes of health systems and educational programs has resulted in policy changes by the government.

Of note, the university's activities are not confined to educational and system development. The department actively conducts research that is guided by health system questions and that guides curriculum. For example, inquiries into maternal management of child illness and household risk factors for child death probe the social determinants of the health transition. And students conduct focus group discussions probing into mothers' perceptions of and response to childhood diarrhea. On a national scale, the department oversees the Maternal and Infant Mortality Survey of 40 000 households in all four

provinces, the results of which will strengthen the university's linkages with the government and guide policy. Moreover, the Pakistan Medical Research Council has asked the department to advise it regarding research priorities and capacity building for research.[10]

What can be said about the *generalizability* of our experience to other universities in developing countries? The salient question is, how feasible is it for universities to engage in health system development? It is feasible, depending on the extent of university interest, commitment, and resources. Faculty and staff must have—or be willing to develop—the relevant disciplinary backgrounds: health system planning and management, epidemiology, and sociopolitical skills to interact with communities and government. Financial resources are necessary for fieldwork and system development; however, field activities can be undertaken at low cost and can greatly stimulate a university's thinking in system development. The *process* of pursuing constructive change under conditions of underdevelopment requires faculty who sensitively press for change and an institutional orientation that rewards advances in education and health system development as well as more conventional research.

Regarding faculty development, our experience can guide similar universities' institutional growth in this field. The lack of trained, interested faculty is a commonly cited obstacle that precludes a university's pursuit of health system development. But our university did not begin with strong expertise in this field. Instead, a few committed senior faculty recruited interested young people and trained them in the field to learn of individual, community, and health system problems and opportunities, while supporting and monitoring their professional maturation. Note that our university is not unique in health system development activities. Many universities in both developed and developing countries have similar missions.[11,12]

The undergraduate educational programs are also generalizable to other universities in developing countries. While other universities have more experience in innovative teaching methods, our strength is our extensive involvement in community-based education in the context of health system development.

This paper adds to the current debate on change in medical and nursing education, including the growing practice of universities to establish community- and population-based education and health care programs.[13] Such institutions accept responsibility for the health of a defined population, this responsibility includes not only involvement in health care guided by epidemiological methods but also advocacy for those populations.[14] The Aga Khan University's experience should encourage other like-minded universities in both developed and developing countries. Indeed, here universities share a common agenda regardless of their societies' development. □

APPENDIX A—Management Training Evolves Into a District Health Management Team (DHMT)

Initiation of training

1. Initiating management training: 22 medical officers selected by participatory approach
2. Trainees planning training: need for trainee participation recognized after first workshop

Growth of individuals

3. Making case studies: "resource trainees" volunteer to help make real-life case studies
4. Making/facilitating modules: resource trainees help design and implement whole modules
5. Identifying new issues: issues beyond the curriculum—transfers, political interference
6. Training trainers: DHO seeks plan, curriculum, and trainers for World Health Organization's VHV Programme

Growth of the team

7. Defining DHMT: as program evolves—new name (DHMT) and terms of reference
8. Expanding role: problem solving—reporting defaulters, low utilization, etc.
9. Increasing participation: female and community participation debated and female joins
10. Team approach: DHMT responds to 2^{0} hospital's request for situation analysis
11. Meeting policy makers: DHMT concept approved for Sindh Province
12. Institutionalizing DHMT: DHMT and DG Health-Sindh review institutionalization

Note. DHO = district health officer; VHV = village health volunteer; DG Health-Sindh = director general of health of Sindh Province.

APPENDIX B—Medical Curriculum: Preclinical and Clinical Courses by Year of Study and Content

Course	Year	Content
		Preclinical phase
Community, health, and development	1	Introduction to development, risk groups, and primary health care in the context of Pakistan and Aga Khan University
Community assessment	1	Epidemiology, biostatistics, demography, and qualitative methods to design/implement/analyze field survey
Health services assessment; occupational health	2	A macroview of assessment and an introduction to Pakistan's occupational health challenges
Primary health care technologies	2	Biomedical, technical, social, and managerial aspects of primary health care components
Planning	2	Equipped with micro- and macroassessment tools plus ranges of strategies and activities, students design a response
Biomedical ethics and clinical epidemiology	3	The ethical and epidemiological dimensions of the clinical and community encounter—a bridge to the clinical years
		Clinical phase
Primary health care technologies	3	Student groups explore technologies: appropriateness, effectiveness, and affordability over 2 months
Research methodology	4	Student groups design, implement, analyze, and report a supervised study over 1 month
Evaluation methodology	5	Student groups perform a detailed evaluation of part of an existing health system over 3 months

Physicians Who Have Practiced in Both the United States and Canada Compare the Systems

Gregory J. Hayes, MD, MPH, Steven C. Hayes, PhD, and Thane Dykstra, BA

ABSTRACT

Objectives. The aim of this study was to examine the US and Canadian systems from the unique perspective of physicians who have practiced in both Canada and the United States.

Methods. Questionnaires were sent to 355 Canadian physicians who graduated from US medical schools and 347 US physicians who graduated from Canadian medical schools.

Results. The overall response rate was 59% (65% of US-graduated Canadian physicians and 54% of Canadian-graduated US physicians). Thirty-six percent of the respondents were "dual experience" physicians; that is, they had practiced medicine in both countries after completing their medical training. Physicians who left Canada were more likely than those who left the United States to indicate dissatisfaction with the health care system as a reason for leaving. Respondents expressed greater professional satisfaction with their current country of practice, but overall, dual-experience physicians in the United States favored that system only slightly more than the Canadian system, whereas those in Canada rated the Canadian system significantly better than the US system.

Conclusions. The comparatively weak rating of the US system by dual-experience physicians underlines the need for health care reform. (*Am J Public Health.* 1993; 83:1544–1548)

Introduction

In the United States, interest in the Canadian health care system is widespread.[1–3] A large percentage of the US public favors extensive health care reform.[4] Proposals for reform have sometimes drawn heavily on the Canadian model,[5] although this model has been viewed with skepticism by others.[6–8] Such skepticism has been fueled by signs of increasing stress within the Canadian system in recent years. Rising costs, efforts at cost control in the face of increasing benefits, and stagnant or depressed earnings among physicians have placed the Canadian health care system in jeopardy.[9–12]

Analytical comparisons between the US and Canadian health care systems can sometimes exclude the human side of the equation.[13–14] Given the close proximity of Canada to the United States, a sizable number of health professionals have had direct experience as providers in both systems. These physicians have a unique perspective that should be of particular interest to those seeking insights into methods of health care delivery. Yet the literature on the subject to date has been limited.[15–17] The current study takes this inquiry a step further.

Methods

Using the 1987 Canadian Medical Directory, we identified all Canadian physicians (488) who had graduated from US medical schools. The use of an older directory allowed for a minimum number of years of professional experience in Canada. A similar-sized group (533) of graduates of Canadian medical schools now practicing in the United States was gathered by identifying the first Canadian medical school graduate on every fifth page of the 1988 American Medical Association Directory. (There are about 17 times more Canadian-graduated US physicians than US-graduated Canadian physicians; each group represents roughly 1% of its respective work force.) Addresses for both groups were then updated, using the 1990 directories for both countries. We sought to identify physicians who had had direct professional experience in both the United States and Canada, without a requirement as to original country of residence. The respondents thus included individuals with a variety of backgrounds and included both Canadian and US citizens who attended medical school outside their own country, some of whom stayed on to receive further medical training or to practice medicine before returning to their own country.

Questionnaires were mailed to 813 physicians so identified for whom current addresses were available. Questionnaires proved deliverable to 702 physicians (355 Canadian and 347 US) and 414 were returned, 232 (65%) from Canadian physicians and 182 (54%) from US physicians (overall response rate, 59%).

Results

Of the 414 respondents, 256 (62%) obtained additional professional training (internships, residencies, and/or fellowships) in the same country as their medical school. Further, 147 respondents (36%)

This paper was accepted April 29, 1993.

practiced medicine in both countries after medical training, averaging 10.43 years of experience in the Canadian system and 10.98 years in the US system. We will refer to this group as "dual experience" physicians.

Men made up 76% of the sample and women 20% (4% did not report their sex). The respondents were predominantly (88%) White. Five percent were Black, Asian, or Hispanic (7% did not report their race/ethnicity). Age was reported in 10-year increments. The predominant age group was 40 through 49 years of age, especially in the Canadian sample, where 49% of all respondents fell into this age group.

Respondents were divided into two groups. "Primary care providers" included those practicing in nonsurgical areas of medicine that traditionally provide primary care services the majority of the time: general practice, family practice, pediatrics, and internal medicine (including geriatric medicine). All others were classified as "non–primary care specialists." The sample consisted of 166 (40%) primary care physicians and 234 (57%) non–primary care specialists (3% did not report their field of practice).

The questionnaire focused on global measures of satisfaction with the respondents' professional experience in each country. Respondents were asked: Overall, how would you rate your level of satisfaction with your experience as a practicing physician? As a practicing physician, how satisfied are you with the financial compensation for your work? As a practicing physician, how satisfied are you with the quality of medicine you have been able to practice? Separate answers were given for each system. Additional questions addressed the impact of cost containment measures and asked each physician to compare the two systems directly, using a single overall rating. For dual-experience physicians, an additional question asked for the reasons they had left their first country of practice. Respondents were invited to expand on their responses with additional narrative.

The 147 dual-experience physicians were of greatest interest; except where noted, all results were drawn from this group, which consisted of 75 Canadian physicians and 72 US physicians. Table 1 summarizes the reasons members of this group left their first country of practice; Table 2 compares the answers of the Canadian and US dual-experience physicians to the global satisfaction questions.

TABLE 1—Percentages of Dual-Experience Physicians Giving Reasons for Leaving Previous Country of Practice

Reason	Physicians Who Left the United States (n = 75)	Physicians Who Left Canada (n = 72)
Generally dissatisfied with system	25	43*
Unable to practice quality of medicine desired	13	29*
Unhappy with financial rewards	5	47**
Personal reason(s) unrelated to problems with the health care system		
In addition to one or more of above	32	28
Personal reason(s) only	48*	39

Note. Except for those who cited personal reasons only, respondents could select more than one reason.
*$P < .05$ (chi-square test); **$P < .001$ (chi-square test).

TABLE 2—Satisfaction of Dual-Experience Physicians with Canadian and US Health Care Systems

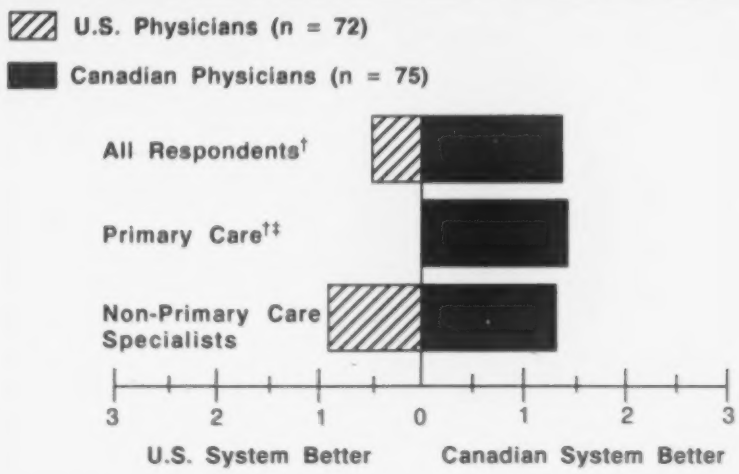
	Primary Care Physicians		Non–Primary Care Specialists		Total Sample	
	Canada (n = 37)	United States (n = 33)	Canada (n = 38)	United States (n = 39)	Canadian Physicians (n = 75)	US Physicians (n = 72)
Level of Satisfaction	Mean (SD)	Mean (SD)	Mean (SD)	Mean (SD)	Mean (SD)	Mean (SD)
Overall, Canada	5.1 (1.4)**	4.0 (2.1)	5.5 (1.0)*	3.9 (1.9)	5.3 (1.3)*	4.0 (2.0)
Overall, United States	3.4 (1.5)	4.9 (1.5)*	4.3 (1.6)	5.1 (1.4)**	3.9 (1.6)	5.0 (1.5)*
With financial compensation, Canada	4.6 (1.7)*	3.3 (1.8)	4.5 (1.6)*	3.4 (1.7)	4.6 (1.6)*	3.4 (1.8)
With financial compensation, United States	4.7 (1.6)	5.4 (1.5)	5.0 (1.0)	5.6 (1.3)**	4.8 (1.3)	5.5 (1.3)*
With quality of medicine able to practice in Canada	5.4 (1.4)**	4.5 (2.0)	5.9 (1.0)*	4.1 (1.8)	5.6 (1.3)*	4.3 (1.9)
With quality of medicine able to practice in United States	4.3 (1.6)	5.3 (1.5)**	4.8 (1.7)	5.9 (0.9)*	4.6 (1.7)	5.6 (1.2)*

*Note. Responses were made on a 7-point scale: 1 = completely dissatisfied, 4 = opinion neutral, 7 = completely satisfied.
*$P < .01$ (unpaired t test); **$P < .05$ (unpaired t test).

Physicians who had left Canada were significantly more likely than their US counterparts to express dissatisfaction with the health care system as a reason for leaving ($P < .05$; financial compensation, $P < .001$). Nearly half (48%) of those who had left the United States did so for strictly personal reasons unrelated to their experience with the US health care system (most commonly employment opportunities).

Physicians' expressions of satisfaction with their professional experience in their current country were significantly better than ratings of that country by physicians who had left ($P < .05$), with the exception of Canadian physicians' expressions of satisfaction with the financial rewards of both systems, which were essentially equal. Further dividing the Table 2 sample into those expressing dissatisfaction with the health care system and those giving only personal reasons (unrelated to the health care system) for switching countries showed that those with strictly personal reasons rated their initial country more highly than those expressing dissatisfaction.

Specialists in both countries indicated levels of satisfaction equal to or



† p<.01 (unpaired t-test, Canadian versus U.S. respondents)

‡ The value for U.S. primary care physicians was zero (a neutral rating)

Note. Values shown express a net absolute value calculated from original survey responses (see text for additional explanation).

FIGURE 1—Strength of support for current system among physicians with experience in both the United States and Canada.

higher than those of primary care physicians. US physicians, both primary care physicians and specialists, were more satisfied with their earning ability in the United States than with their previous earning ability in Canada. Canadian specialists were more satisfied with levels of compensation in the United States than in Canada, but to a lesser degree than their US counterparts, whereas Canadian primary care physicians expressed essentially equal satisfaction with their income in both countries.

Regarding the effect of cost containment measures on their ability to practice, both Canadian and US physicians indicated only a slight to moderately negative impact. There was no statistically significant difference between the two groups, except that Canadian specialists viewed US efforts at cost containment more negatively than did US specialists ($P < .05$).

Juxtaposed against the preceding data, the answers to the question "How would you rate the Canadian and US health systems in comparison to each other?" were unexpected. Each group again favored its current country, with the exception that US physicians who had left Canada for strictly personal reasons rated the Canadian system slightly better. The strength of response, however, was significantly different. For this question, responses given on a 7-point scale (1 = US system better, 7 = Canadian system better) were subtracted from the question's neutral rating of 4. The absolute net value of this calculation is seen in Figure 1, which demonstrates, in an overall sense, the strength of dual-experience physicians' rating of their current country over their previous one: Canadian physicians' rating of their own system was three times greater in strength than US physicians' rating of the US system ($P < .01$). Among all respondents, the Canadian physicians' rating of their current system was more than four times greater in strength than the US physicians' rating of the US system ($P < .01$).

It is useful to further divide the dual-experience group based on the time period in which practice experience occurred: those who, at least in part, practiced in both countries between 1970 and 1980 (n = 112) and those whose practice experience in both countries included years after 1980 (n = 99). The first group had the opportunity to experience the US Medicare and Medicaid programs begun in the mid-1960s as well as Canada's shift to its provincially based system, which was complete by 1972. (Most governmental programs for hospital coverage in Canada began in the late 1950s and were in place by the mid-1960s in all provinces; most governmental outpatient programs began in the mid-1960s and were in place in all provinces by 1972.) The second group had the chance to experience the more recent strains on the Canadian system as well as the institution of diagnosis-related groups in the United States.

When results from these subgroups were compared with those of the entire dual-experience group, only two important differences were seen. Among US physicians who left Canada sometime after 1970, mean values for overall satisfaction with the Canadian system as well as for quality of care and financial compensation in that system were somewhat lower than values in the entire group of US dual-experience physicians. In the subgroup of US physicians who had left Canada after 1980, a similar drop in mean values was seen regarding the level of compensation in Canada. All other fluctuations in mean values were minimal. Overall, the differences shown in Figure 1 were not substantially altered when we focused on physicians with more up-to-date experience in both systems.

Comment

As an important information source, physicians who have had direct professional experience in both Canada and the United States have been underutilized. These individuals have been "in the trenches" on both sides of the border and have seen how each system works on a day-to-day basis. Their input is a valuable addition to more theoretical analyses. In identifying every US-graduated Canadian physician and a similar-sized sample of Canadian-graduated US physicians, we sought to harness the real-life perspective of these unique groups.

These groups may not be representative of all Canadian or US physicians. In addition, the respondents were self-selected and may not be the same as nonrespondents. An analysis of respondents to the first and second mailings provides some information on this issue, since initial nonrespondents became part of the second group of respondents. We used simple *t* tests to compare all measures for these two groups. Only one of 16 comparisons was significant; this was approximately the number of differences expected on the basis of chance alone at $P = .05$. Respondents to the first mailing rated the US system significantly more highly than did second-mailing respondents. If such a difference is real, subsequent mailings to nonrespondents would

only be expected to strengthen the results we obtained. Thus there is little reason, based on the data themselves, to suspect that if more opinions from nonrespondents were included, different conclusions would be reached.

The evolution of Canada's single-payer system was associated with protests from physician groups who feared governmental involvement. Those less enamored of the radical changes occurring in Canadian health care may have been more likely to leave when the opportunity arose. Thus, on the one hand, we expected the results summarized in Table 1: physicians who chose to leave Canada more commonly expressed dissatisfaction with the system as a reason for leaving than did their counterparts who left the United States. Yet levels of satisfaction with their current country were essentially equal: Canadian physicians were generally as satisfied with their professional experience as were US physicians, and they were reasonably satisfied with their financial rewards (Table 2). Further, notwithstanding the knowledge that their income would be greater in the United States, Canadian specialists in our sample expressed relative contentment with their practices as measured by levels of overall satisfaction and satisfaction with the quality of medicine they are able to practice. In both cases these indicators were equivalent to those of US specialists.

The most unexpected result was the relatively weak rating of the US system by US dual-experience physicians (Figure 1). We had expected a stronger rating of the US system by these US physicians as compared with the rating of the Canadian system by Canadian physicians, both because dissatisfaction with the health care system was more commonly expressed by physicians leaving Canada for the United States and because financial remuneration in the United States is greater. In this survey, the opposite proved the case. This result is not clearly explained by the global measures of satisfaction previously described, but it is partly accounted for by the fact that among physicians who moved from one country to the other for strictly personal reasons, current US physicians rated Canada slightly better while Canadian physicians strongly favored Canada. Although both US and Canadian physicians were reasonably and equally satisfied with their current practices, a compilation of solicited comments from the current survey offers some potential clues to explain the results summarized in Figure 1.

Three issues were most often raised in the respondents' comments: access to care, administrative responsibilities, and medical malpractice. These issues were consistent with previously acknowledged strong points within the Canadian system.[2,3] The need for better access to care in the United States, a widely discussed issue in the current literature,[18,19] was by far the most common concern expressed. It appeared that once physicians had experienced the positive effects of universal access (in Canada), it was difficult to accept their absence (in the United States). Universal access was seen as a major benefit not only to the patient but to the practitioner, who no longer needed to worry about the patient's ability to pay in determining a course of action.

The inefficient paperwork jungle common to US health care[20,21] was contrasted with the simplified administrative tasks of the Canadian system. Although the comments indicated that administrative requirements were increasing in Canada, Canada's provincially run, single-payer system remained extraordinarily simple compared with the US system. Although respondents were often concerned with the administrative overload in the United States, there was essentially no call for a single-payer system. Rather, the overall sentiment was in favor of maintaining a public-private insurance structure but with sufficient changes to decrease the administrative burden.

Medical malpractice was seen as a serious issue in both countries. The number of lawsuits has increased in both Canada and the United States. Canadian physicians expressed concern with the trend. Yet for dual-experience physicians the problems with medical malpractice in Canada paled in comparison with those in the United States. Even today, "Canadian physicians are only one fifth as likely to be sued for malpractice as their American counterparts."[22]

Nevertheless, it should be emphasized that physicians who left Canada were clearly more satisfied with their practices in the United States than in Canada. Their responses should not be construed as a call for the "Canadianization" of the US health care system. Rather, the message was that the United States should seek to learn from the successes of others. Instead of being the experimenter, the US system can take what has worked elsewhere and combine it with its own many strengths. Examples of how this might be done may come from Canada, from other countries,[23-25] or from within our own country.[26,27]

The weak rating of the US system by US dual-experience physicians can reasonably be interpreted as a call for a more careful analysis and probable reform of at least certain aspects of the US system, including issues of access, administrative burdens, and malpractice costs. The data gathered in this study, especially considering the generally conservative nature of physicians as a group, emphasize the need for change in the way health care is provided in the United States. □

The Effects of a Natural Disaster on Child Behavior: Evidence for Posttraumatic Stress

ABSTRACT

Objectives. A prospective study of children examined both before and after a flood disaster in Bangladesh is used to test the hypothesis that stressful events play a causal role in the development of behavioral disorders in children.

Methods. Six months before the disaster, structured measures of selected behavioral problems were made during an epidemiological study of disability among 2- to 9-year-old children. Five months after the disaster, a representative sample of 162 surviving children was reevaluated.

Results. Between the pre- and postflood assessments, the prevalence of aggressive behavior increased from zero to nearly 10%, and 45 of the 134 children who had bladder control before the flood (34%) developed enuresis.

Conclusions. These results help define what may be considered symptoms of posttraumatic distress in childhood; they also contribute to mounting evidence of the need to develop and evaluate interventions aimed at ameliorating the behavioral and psychological consequences of children's exposure to extreme and traumatic situations. (*Am J Public Health.* 1993;83:1549–1553)

Introduction

Stressful life events have long been suspected of causing behavioral and emotional disorders in children,[1,2] but their true causal role is difficult to distinguish in a controlled manner from effects.[3] Clearly defined events such as disasters can be distinguished from effects of a child's behavior because they occur independently of the behavior and because their timing in relation to the behavior is unambiguous. Unfortunately, methodological weaknesses[4] and the inconsistency between studies render the literature on children who have survived disasters,[5–14] wars,[1,15–18] and other acute events[19–21] inconclusive with regard to emotional and behavioral effects. Some studies report excess levels of anxiety, depression, and/or behavioral problems including aggression, enuresis, and eating and sleeping disorders,[1,5–7,9–11,15,18,19] while others report no apparent adverse effects on behavior or on psychological well-being.[8,12,14,16,17]

The present study used the strongest feasible design, a natural experiment, to investigate this issue. Natural experiments are prospective studies in which investigators can systematically observe the outcome of interest in a population both before and after a well-demarcated exposure or event.[22] Only two previously published studies of children exposed to severe events were able to use such a design; in one, 85 Israeli children (aged 10 to 11 years) were studied before and during war[18]; in the other, 64 American children (aged 4 years) were studied before and after a storm disaster.[7] In both studies, the prevalence of psychological distress symptoms increased significantly after the exposure compared with baseline. At the same time, neither study found evidence of a linear or dose-response relationship between the severity of the event for individual children and the probability of those children exhibiting symptoms.

The present study observed a larger number of children (162) and a wider age range (2 to 9 years) than the two previous prospective studies. In September 1988, 6 months after our international team completed a population-based study of child health and disability in Bangladesh, a flood disaster occurred. It was the most severe ever recorded in this densely populated country. More than three quarters of the land was submerged, much of it for 20 days or more. Throughout the country, millions of people were left homeless and more than 2000 died as an immediate consequence.[23] Five months after the flood (in February and March 1989), a representative sample of children evaluated during the initial survey was selected for reevaluation. We hypothesized that, despite maturation of the cohort, the prevalence of aggression, extreme shyness, and enuresis would be significantly higher after the flood than before.

TABLE 1—Baseline Characteristics of Those Children Selected for Follow-Up and of Those Children Followed

	Children Selected for Follow-Up, % (n = 204)	Children Followed, % (n = 162)
Sex		
Boys	51.5	52.5
Girls	48.5	47.5
Age, y		
2	9.3	6.8
3	7.8	8.6
4	7.8	13.6
5	7.8	8.0
6	9.3	9.3
7	22.6	21.0
8	19.1	14.8
9	16.2	17.9
Disability status		
Not disabled	68.6	69.8
Disabled[a]	31.4	30.2
Cognitive disability	12.6	11.7
Motor disability	3.9	4.9
Hearing disability	11.9	13.0
Vision disability	2.9	3.1
Seizure disability	2.5	1.9

[a]Thirteen children selected for follow-up and seven children followed had multiple disabilities.

Methods

Study Sample

In March 1988, we completed a population-based study of neurodevelopmental disabilities in 2667 2- to 9-year-old children representative of Dhamrai, a rural, agricultural community north of Dhaka, Bangladesh. Households generally included nuclear and extended families; homes were built of reed and mud with earth flooring and one or two rooms. Half of the fathers and a quarter of the mothers had attended any level of primary school. All children who tested positive for disability on the Ten Questions screening instrument and a 10% random sample of those who tested negative were referred for standard clinical evaluations by a pediatrician and a psychologist, and a structured interview was conducted with a parent or guardian.[24–29] In all, 434 children were referred for evaluations and 64 were judged to have disabilities.

After the September 1988 flood, some of the children who were initially evaluated were selected for reevaluation, including all 64 with disabilities and a random sample (140) of the remainder (no more than one child per household). Of those, 2 children, 1 of whom had a disability, had died from diarrheal disease after the flood; moreover, 14 children with disabilities and 26 other children could not be traced (see Table 1). Thus, in February 1989, 162 children (49 disabled and 113 not disabled) were reevaluated.

Testing Instruments

During the postflood evaluation, the pediatricians asked the identical two questions about aggression and shyness that were asked before the flood (Appendix). However, the psychologists asked the question on sphincter control in different but comparable ways on the two occasions (Appendix).

The postflood psychological assessment added a child behavior screening scale administered to parents: the Richman Child Behavior Checklist[30] for children aged 3 to 6 years at follow-up and the Rutter Child Behavior Questionnaire[31] for those aged 7 to 10 years at follow-up. These brief and simple instruments are reliable and valid indicators of psychopathology and are widely used in culturally diverse populations.[30–32] In addition, the Self-Reporting Questionnaire[33] (a measure of psychological distress) was asked of the mother.

Each of these three scales was translated into Bangla, backtranslated, and revised appropriately. Internal consistency reliability coefficients (lower-bound estimates of reliability[34]) were good to excellent: 0.78 for the Richman checklist, 0.67 for the Rutter questionnaire, and 0.60 for the Self Reporting Questionnaire. Finally, a structured questionnaire measured the flood experiences of the community.

Statistical Analyses

The McNemar test[35,36] was used to test differences in the prevalence of problems before and after the disaster. T tests[37] were used to assess the differences in mean scores of postdisaster behavior scales between children reported to be aggressive after the flood and other children. Logistic regression[38] analyses were used to test for the effects of age, gender, disability, and severity of the disaster experiences on the dichotomous behavior outcomes (e.g., postdisaster onset of enuresis and aggressive behavior). Chi-square tests[36] were used to assess the significance of associations between the occurrence of two behavioral problems (aggression and enuresis). Lastly, the Taylor series method was used to calculate confidence intervals for the ratios of post- to preflood prevalence of incontinence.[39]

Results

The postflood survey documented major effects of the flood on the 162 households. Less than 10% had any warning of the flood. In more than a third, water rose to a level higher than an adult's waist, and more than half remained flooded after 10 days. Thirty-eight percent were badly damaged or destroyed. In half of the families, at least one member became seriously ill; in 7% a household member died, and in 4% the child was separated from the parents for more than a day.

Behavior

Before the flood, no child was reported to be very aggressive, and only one was reported to be extremely shy and withdrawn (Table 2). Twenty-seven (16.8%) had problems with sphincter control (bowel and/or bladder). After the flood, 16 children were newly reported to be very aggressive ($P < .0001$), shyness persisted in one affected child, and lack of sphincter control had increased from 16.8% to 40.4% ($P < .0001$). The increases in aggression and incontinence occurred among both children with and without disabilities and regardless of gender. (Although 11.8% of boys developed aggressive behavior compared with 7.8% of girls, this gender difference is not statistically significant in a logistic regression analysis.) Aggressive behavior increased at nearly every age. (Numbers are small, and specific age differences are not significant.)

Mean scores on the Richman checklist and the Rutter questionnaire (overall and on the conduct disorder subscale but not on the neurotic subscale) were significantly higher for children reported to be aggressive than for other children. The mean scores on the measure of psychological distress (the Self Reporting Questionnaire) were not significantly higher for mothers of children reported to be very aggressive than for mothers of other children.

For incontinence, the prevalence more than doubled (prevalence ratio 2.41, Table 2.) The increases were somewhat greater for children without disabilities than for those with disabilities, and for boys than for girls, but these increases are not statistically significant ($P = .57$ and $P = .50$, respectively, on logistic regression analysis). With no aggressive behavior observed at the preflood assessment, prevalence ratios for aggression could not be calculated.

The single question about sphincter control asked before the flood did not allow bladder control to be distinguished from bowel control. The postflood questions did

allow this distinction. The increased prevalence of incontinence after the flood was owing entirely to new cases of enuresis. Among 134 children continent before the flood, none developed encopresis while 45 developed enuresis. All enuresis was nocturnal in children aged 3 to 6 years. (At 7 to 10 years, night and day wetting could not be distinguished.)

Incontinence

Before the flood, age-specific prevalence rates were as expected, with very high rates for 2- to 4-year-old children and much diminished prevalence thereafter (Figure 1). After the flood, the pattern differs from that expected. In children aged 2 and 3 years before the flood, prevalence declined less than expected, with maturation over a period of 11 months. In those aged 4 to 9 years, prevalence increased substantially.

Among younger children (3 to 8 years at follow-up), the risk of developing enuresis was high and relatively uniform (37% to 45%). At the oldest ages (9 to 10 years at follow-up), the risk was significantly lower (χ^2 vs all younger children = 6.47; $P = .011$) but still substantial (21%).

Twenty of 28 children wetting or soiling before the flood were still doing so after (with postflood data missing for 1 child). Another 45 previously continent children had "onset enuresis" at the second assessment, at a mean age of 6.3 years vs 2.9 years for those not yet toilet trained.

Aggression and Enuresis

We compared postflood development of aggression in three mutually exclusive groups with respect to continence: (1) those continent at both assessments (pre- and postflood), (2) those incontinent at the preflood evaluation; and (3) those continent before the flood and enuretic postflood (Table 3). Children incontinent before the flood had twice the prevalence of postflood aggressive behavior as other children ($\chi^2 = 2.20$; $P = .333$, not significant).

Household experiences varied in terms of depth of water, degree of damage, illness, and loss. On logistic regression analyses, however, we found no relation between the severity of the flood experiences in individual children and the development of behavioral problems.

Discussion

In accordance with our prior hypothesis and with previous studies, the prevalence of both aggressive behavior and enuresis in children rose sharply after exposure to major environmental stress. The observed increase in enuresis is particularly striking when one considers that the cohort had matured nearly 1 year between the first and second assessments.

Onset enuresis has long been considered a marker for anxiety, but experimental findings are rare. Control of the bladder during sleep is a subtle balancing act that requires either the child to wake to the stimulus of the full bladder (and get out of bed to void) or the sphincter to stay shut while the bladder is signaled to expand. For the sleeping child to lose a previously acquired skill, one need not invoke factors such as bladder size, depth of sleep, or cognition. Regression of bladder control such as that observed after the flood may imply autonomic system incoordination occurring at an age when the system is susceptible to being thrown off balance by an upsetting experience. As the child matures, the system stabilizes and regression is less likely. In Bangladesh, it appears that both regression and primary delay in sphincter control may have taken place. Previous studies have tended to associate regression rather than delay with emotional disturbance.[40-43]

Both increased aggression and onset enuresis were reported in Freud and Burl-

TABLE 2—Frequency of Selected Behavioral Problems Recorded during the Clinical Assessment before and after the Flood

	Before		After			Prevalence Ratio (95% Confidence Interval)[b]
	No.	%	No.	%	P[a]	
Very aggressive toward others						
All children (n = 162)	0		16	9.9	<.0001	
Nondisabled children (n = 113)	0		10	8.8	.0020	
Disabled children (n = 49)	0		6	12.2	.0313	
Boys (n = 85)	0		10	11.8	.0020	
Girls (n = 77)	0		6	7.8	.0313	
Extremely shy/withdrawn						
All children (n = 162)	1	0.6	1	0.6	1.0000	1.00
Lack of sphincter control[c]						
All children (n = 161)[d]	27	16.8	65	40.4	<.0001	2.41 (1.63, 3.56)
Nondisabled children (n = 112)	18	16.1	48	42.9	<.0001	2.67 (1.21, 3.19)
Disabled children (n = 49)	9	18.4	17	34.7	.0768	1.89 (0.93, 3.82)
Boys (n = 85)	10	11.8	35	41.2	<.0001	3.50 (1.85, 6.61)
Girls (n = 76)	17	22.4	30	39.5	.0106	1.76 (1.07, 2.92)

[a]McNemar test of the significance of the difference between the proportions affected before and after the flood.
[b]Prevalence ratio for aggression cannot be calculated because of zero prevalence in the denominator (i.e., before the flood).
[c]The question asked before the flood referred to enuresis and/or encopresis. After the flood, separate questions were asked about enuresis and encopresis. The increased prevalence after the flood is owing solely to new cases of enuresis.
[d]Excluded is one child who was not fully toilet trained at baseline (a nondisabled girl, age 3) and who had missing information about enuresis and encopresis after the flood.

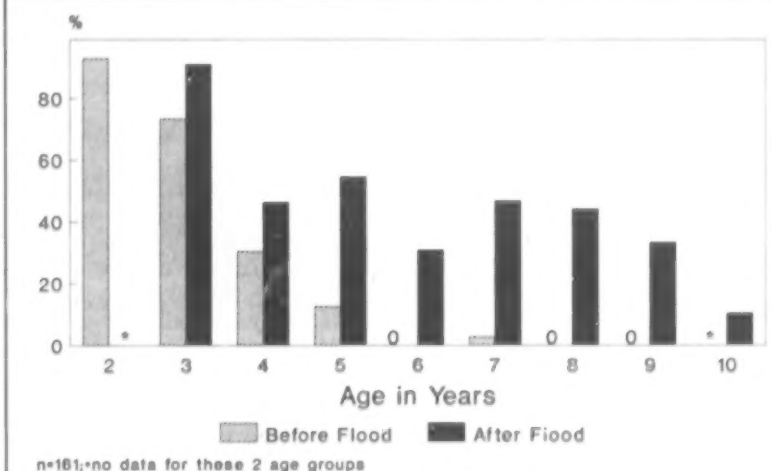

FIGURE 1—Prevalence of incontinence by age, before and after the flood.

TABLE 3—Cross-Tabulation of Enuresis Status by Postflood Development of Aggressive Behavior

Behavior, %	Total	Prevalence of Postflood Aggressive Behavior, %
Continent at pre- and postflood evaluation	89	6.7[a]
Incontinent at preflood evaluation	28	14.3
Continent at preflood evaluation, enuretic at postflood evaluation	45	13.3
Total	162	9.9

[a]The lower prevalence of aggressive behavior in this group is not statistically different from that of the other two groups combined ($\chi^2 = 2.20$; $P = .333$).

ingham's[1] detailed observations of children in shelters (war nurseries) during the World War II bombings of London, and were interpreted as regressive behaviors provoked by children's separation from their parents and the overwhelming stresses of wartime. Similar observations of increases in both aggressive behavior and enuresis were made among 198 children discharged from a hospital burn unit compared with a comparison group of uninjured siblings.[44] Aggressive behavior and/or enuresis have also been reported in studies of children during the aftermath of a wide variety of disasters including an earthquake,[8] Australian bushfires,[9] a school disaster,[11] a flood disaster,[10] a lightning-strike disaster,[6] a tornado,[5] and a cyclone.[15] In addition to aggressive behavior and onset enuresis, many of these studies also reported increased anxiety, specific fears, and eating and sleep disorders.

One third of the sample of children selected for study in Bangladesh had disabilities at baseline; the remainder was a representative sample of the rural population under study. The increase in both aggression and enuresis observed after the flood was similar in the disabled and nondisabled samples. While the possibility remains that the flood could have affected children with specific types of disabilities differentially, the numbers with any one type of disability do not permit further evaluation.

The increases in aggression and enuresis occurred in both boys and girls. However, consistent with other descriptive epidemiological studies,[30,31,45,46] rates tended to be higher in boys.

The preflood rates in 7- to 9-year-old children both of aggressive behavior (none reported) and of enuresis (less than 2%) are lower in this population in Bangladesh than in European populations,[31,47–51] where prevalence rates for this age group range from 5% to 15% for aggressive behavior and from 6% to 10% for enuresis. In at least one study other than this one,[52] Asian children showed fewer behavioral problems than their European or American counterparts.

Consistent with the findings of the two previous prospective studies,[7,18] no dose response for individual children was observed between the severity of disaster experiences and behavior. One possible explanation for this is that an association was present but was confounded by unmeasured differences between households in resources that ameliorated the effects of the disaster. Another is that the disruption resulting from disasters and war is pervasive and communitywide. Thus, the relevant exposure is not the degree of household destruction and danger, but the overall disruption and terror experienced by the population as a whole.

One limitation of this study is that the follow-up was restricted to 5 months after the disaster, leaving uncertain the duration of aggressive behavior and enuresis. Another limitation is the absence of diagnostic evaluations before and after the flood that would have allowed us to determine whether exposure to the disaster resulted in an increased prevalence of actual psychopathology and/or of symptoms other than aggression and enuresis. From the significant associations between the single question on aggressive behavior and the Richman and Rutter behavior scales, we infer that this question, asked both before and after the disaster, appears to have validity. We may also infer that the aggression rating was not connected to stress in the mother since maternal psychological distress was not significantly higher for mothers of children reported to be very aggressive than for mothers of other children.

The results from this study are compatible with the hypothesis that children's exposure to stressful events may play a causal role in the development of psychiatric disorders. They point to the need for further research, particularly in populations at high risk for stressful events such as disasters, which cannot be confused with events precipitated by a child's own behavior. In addition, the mounting evidence to which this study contributes highlights the need to develop and evaluate interventions aimed at ameliorating the behavioral and psychological consequences of disasters and other extreme situations. □

Acknowledgments

This research was supported by grants from the National Academy of Sciences (USA) BOSTID Program (REA–BD–2–87–69) and the National Institute of Neurological Diseases and Stroke (USA) (R29–NS27971–01, R29–NS27971–02, and R29–NS27971–03).

The authors would like to acknowledge Dr Patrick Shrout for his initial suggestion to do the follow-up study that made this research possible, Wei Wang for providing statistical and computer programming assistance, the field staff in Bangladesh, and the subjects who volunteered their time to participate in this study.

APPENDIX—Behavior Questions Asked during the Medical Assessment before and after the Flood:

Does he/she act very aggressively toward other people?
1. No 2. Yes

Does he/she act extremely withdrawn and shy?
1. No 2. Yes

Questions about sphincter control asked during the psychological assessment

A. Before the flood:
Does he/she have bowel and bladder control; is he/she toilet trained?
1. Yes, like others his/her age
2. Not consistent
3. No

B. After the flood:
In each set below, specify which applies to your child. For 3- to 6-year-olds (from the Richman Child Behavior Checklist)[30]:
1. Never wets at night
Wets the bed up to once or twice a week
Wets the bed three or more times a week
2. Never wets during the day
Wets during the day once or twice a week
Wets during the day three or more times a week
3. Completely bowel trained. Never dirties pants.
Occasionally soils, up to once or twice a week.
Soils pants 3 or more times a week.

For 7- to 10-year-olds (from the Rutter Child Behavior Questionnaire)[31]:
1. Wets his or her pants:
Never in the last year
Less often than once per month
At least once per month
At least once per week
2. Soils him/herself or loses control of bowels:
Never in the last year
Less often than once per month
At least once per month
At least once per week

Water Cost and Availability: Key Determinants of Family Hygiene in a Peruvian Shantytown

Robert H. Gilman, MD, Grace S. Marquis, MS, Gladys Ventura, BS, Miguel Campos, MD, William Spira, PhD, and Fernando Diaz, MD

ABSTRACT

Objectives. This study was conducted to determine whether poor hygiene practices are owing to difficulty in getting enough water and/or to ignorance of sanitary principles.

Methods. In a water-scarce shantytown in Lima, Peru, we observed in 12-hour periods over 3 consecutive days the amount of water and soap used for personal and domestic activities in 53 families and the frequency with which direct fecal contamination of hands was interrupted by washing. We also surveyed women in a similar shantytown concerning their knowledge of hygiene to ascertain whether noncompliance was owing to ignorance.

Results. Three hundred fecal contamination events were registered, of which only 38 (13%) were interrupted by hand washing within 15 minutes. The mean 12-hour per capita amount of water and soap used by the families was low. More than 80% of the water stored by these families had fecal coliforms. Yet the level of knowledge concerning the importance of hand washing and other hygienic practices was high.

Conclusions. In water-scarce areas, sanitary education programs probably will not change hygiene practices. In these areas, an adequate supply of water is essential for good hygiene. (*Am J Public Health.* 1993; 83:1554–1558)

Introduction

Hand washing is an effective means of interrupting fecal-oral transmission and decreasing the intrafamiliar spread of diarrheal disease pathogens such as shigella.[1–4] Poor hygiene practices may be due to ignorance of sanitary principles, high cost, scarcity of clean water, or distance from it.[5–8] When water is plentiful, programs that emphasize hygiene education increase personal sanitation practices and result in decreased rates of diarrhea.[9,10] However, educational messages may not succeed if adequate and convenient water supplies are not available.[11]

Water is a scarce resource in Lima shantytowns called *pueblo jovenes.*[12,13] To describe the effect of water scarcity on sanitary behavior, we used direct observation to determine hygienic practices in such a town.

Methods

Study Sites

The study was carried out in 1987, prior to the cholera epidemic, in two well-described periurban *pueblo jovenes* of Lima, Peru: Huáscar, Canto Grande, and Las Pampas de San Juan de Miraflores.[13,14]

Family Selection

Our study population consisted of families living in Canto Grande who were previously selected at random to participate in a longitudinal diarrhea study.[13,14] Fifty-three of these families, all with at least one child less than 3 years of age, were chosen for the current study. Although all families were impoverished, a skilled field-worker classified them into three ascending grades of wealth.

Differences in income (based on family expenditure data) in a *pueblo joven* are small, varying by less than $1500 per year between families. Seventeen families were selected with equal numbers in each wealth category to determine if that small difference in income affected water and soap consumption. No difference was found, and the remaining 36 families were selected from the randomly generated list without further stratification for wealth. There was no difference between the two groups in their mean socioeconomic status, family size, or water and soap use; therefore, both data sets were pooled and analyzed together.

Detailed In-House Methodology

Hygiene activities. Three consecutive days of 12-hour (7 AM to 7 PM) in-house observation were scheduled with mothers. During the observation period, the field-worker noted the activities of each family member, including preparation and consumption of food and water, defecation, handling of children's feces, and bathing and washing of hands. The field-workers engaged in small talk and avoided all comments concerning soap and water use. Children were asked

This paper was accepted April 29, 1993.

whether they had defecated when they used the household borehole latrine or the nearby hillside. However, because adults were not similarly questioned about these activities, the defecations that were recorded were limited to those spontaneously mentioned by the adults or their children. Adult fecal contamination events are therefore probably underestimated. The type of water (fresh or reused) and soap (face, clothes, shampoo, or detergent) used by each family member was documented. The field-worker noted how often the mother observed her children drinking water that had not been boiled and permitted them to do so.

A contamination event was defined as a family member having just defecated or handled fecally contaminated material such as diapers. An interruption event was defined as the family member hand washing with water or with water and soap within 12 hours of the contamination event.

TABLE 1—Water and Soap Usage after Fecal Contamination: Percentage of Events,[a] by Family Role and Age

[a]Based on events reported during 3 days of 12-hour observation periods.
[b]>10-year-old group does not include mothers.

Total water and soap use. The field-worker observed whether water obtained from the storage tank was boiled before it was drunk. She also noted how much water was used for washing dishes, food, and laundry, and for cleaning house. To facilitate the measurement of water, mothers were provided with a 1-L graduated pitcher. The field-worker weighed all soap at the beginning and end of each 12-hour observation period and noted the type of soap (but not the number of grams) used for each activity. Other household staples were weighed at the same time in order not to call attention to the measurement of the soap.

Water bacteriology. Quality of water stored outside the house was tested in 44 of the 53 Canto Grande families. Samples of 100 mL in sterile bottles were taken from the household cement tank (n = 35) or metal cylinder (n = 9). Fecal contamination of the water was determined by the presence of presumptive coliforms, heterotrophic plate counts,[15] and viable counts of *Aeromonas* and *Vibrio cholerae* sero group non-01. Counts of *Aeromonas* and *Vibrio* species were performed as previously described.[16–19]

Water attitudes and beliefs survey. We also surveyed 107 randomly selected families living in Las Pampas de San Juan to document their knowledge regarding the use of water, hand washing, and bathing. This *pueblo joven,* although different from Canto Grande, is socioeconomically similar.[13] The survey identified the mothers' perceptions of the health risks of not washing hands after fecal contamination and of drinking water that had not been boiled. Mothers were also asked whether water should be stored covered and, if so, why, and whether they drank water that was not boiled. They were also asked at what age and how often babies should be bathed.

Statistical Analysis

Activities were analyzed by age and sex and presented in frequency tables. We followed contamination events over time, using survival curves to determine rates and time intervals of the interruption of fecal-hand contamination. Life tables were used to examine, first, the duration between contamination and hand washing and, second, the duration between uninterrupted contamination and an episode of transmission. These curves were based on the following assumptions: (1) fecal contamination persisted if uninterrupted for at least a 12-hour period; and (2) handwashing, whether with soap or with water alone, stopped fecal transmission.[1] Handwashing that occurred within 15 minutes of a fecal contamination event was considered to be a purposeful interruption. Interruption after this time was defined as unintentional.

Mean daily soap and water consumption was tabulated, and the variances for each day were compared for homogeneity using Bartlett's test.[20] Pearson's correlation coefficients and linear stepwise regressions for the per capita amounts of water and soap used over 3 days were performed with the following variables: the field-worker's socioeconomic evaluation of the families, a housing quality scale (the concordance between the field-worker's scale and a previously described housing quality scale was good, McNemar test),[20] and the mother's and father's education. We also examined the correlation between the percentage of uninterrupted fecal contamination events by each mother and the above variables, as well as the total amount of water and soap used.

Plate counts, fecal coliforms, and individual and combined *Aeromonas* and *Vibrio* counts were tabulated, and linear regressions were run with the socioeconomic and total water and soap usage variables described above.

Results

Contamination and Transmission Events

Family hygienic practices were observed in 53 Canto Grande families for a total of 1872 hours. There were 300 fecal contamination events registered, of which only 38 (13%) were interrupted by hand washing within 15 minutes (Table 1). There were significantly fewer contamination events interrupted in children under 10 years of age than in family members over 10 years of age (odds ratio [OR] = 0.275, 95% confidence interval [CI] = 0.13, 0.588). Soap was used in less than one half (10/38) of the intentionally interrupted events in both age groups. No socioeconomic or demographic characteristics identified which individuals interrupted fecal transmission (using a step-

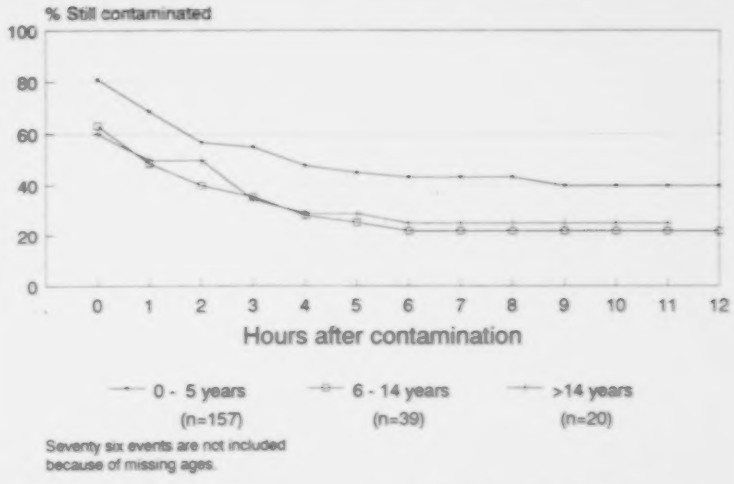

FIGURE 1—Interruption of fecal contamination by hand washing in 216 events.

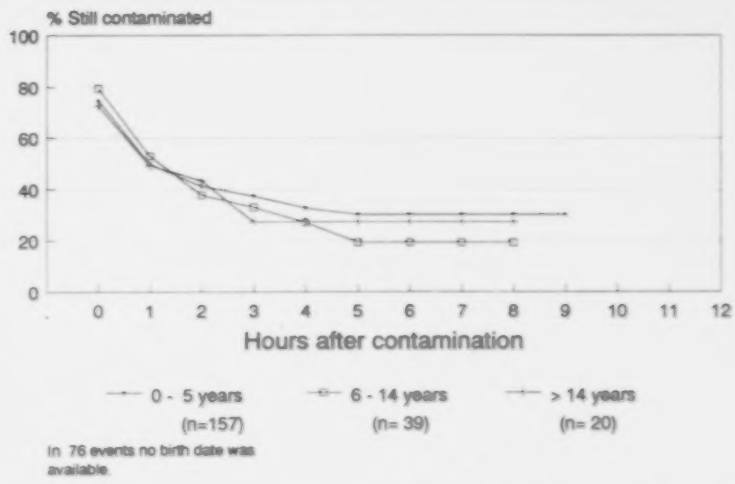

FIGURE 2—Transmission of fecal material from hands to food or water in 216 events.

wise regression model). However, the percentage of mothers' events that were interrupted after fecal contamination had occurred was significantly associated with the total amount of water used by the family ($r = .42$; $P < .05$). Also, the percentage of times that mothers washed their hands prior to eating or preparing food was associated with the total grams of soap used ($r = .42$; $P < .01$) and the fieldworker's economic evaluation of the family ($r = .57$; $P < .001$).

There were 3593 eating, preparing, and serving events observed, of which only 834 (23%) were preceded by hand washing within 15 minutes. The younger age group showed a significantly lower number of these events preceded by hand washing than did individuals over 10 years old (OR = 0.41, 95% CI = 0.34, 0.48). Soap was used significantly less often with hand washing before eating or handling food than after defecating (OR = 0.15, 95% CI = 0.07, 0.31). Soap use was not noted in 12 events.

Survival curves showed that most of the contamination episodes were uninterrupted during the first several hours of observation (Figure 1). Within an hour, more than 20% of individuals with contaminated fingers handled food, thus permitting the potential transfer of enteropathogens to other individuals (Figure 2). More than 25% of all contamination events were not interrupted. Moreover, 70% of contamination events became a transmission event.

Water and Soap Usage Patterns

The amount of water, as well as of soap, used by the family during the three 12-hour periods of observation did not vary significantly over the 3 days. The mean 12-hour per capita amount of water and soap used in the 53 families (mean family size was 5) was extremely low (8.8 +/− 3.8 L of water and 8.6 +/− 6.0 g of soap). About half of the water and nearly all of the soap (in the form of either detergent or laundry soap) was used for washing clothes (Table 2). Less than 15% of the total water was used for bathing and hand washing. Fewer than half (16/39) of the children 0 to 2 years of age and one fourth (12/48) of the 2- to 5-year-olds were bathed at least once during the 3 days of observation.

Most (87%) of the drinking water was consumed after boiling (normally as teas). Not only was more unboiled water drunk by older children but mothers permitted older children to consume such water and observed them doing so significantly more often ($\chi^2 = 11.6$; $P = .003$) than they did younger children (see Table 3).

Hand washing infrequently occurred with face soap, laundry soap, or detergent (Table 1). During the 3-day observation period, four families did not have any type of soap available for 1 of 3 days.

Socioeconomic factors and water usage. There was a weak but statistically significant association between total water used and mothers' education ($r = .3$; $P < .05$). Socioeconomic variables were not associated with total soap use. However, there was a significant association between the amount of total soap and total water used ($r = .66$; $P < .001$).

Water bacteriology. Ninety-five percent (42/44) of the houses sampled had a heterotrophic plate count of more than 500 colony-forming units (CFU)/mL, the standard for acceptable potable water.[15] More than three quarters of the 44 water samples had presumptive fecal coliforms present (Table 4).

In addition, half the families had *Aeromonas* species and almost one third had non-01 *Vibrio cholerae* isolated from their water. *V. cholerae* and *Aeromonas* species counts did not correlate with fecal coliforms counts.

There was no association between the fecal coliform count and either socioeconomic characteristics or quantity of water and soap used during the 12-hour observation period.

Comparative water supply and costs. Families used an average of 58 L of water

TABLE 2—Mean 12-Hour Water and Soap Use in Canto Grande Families (n = 53)

	Mean	Standard Deviation

Detergent	29.8	48.9
Total	53.6	55.3

per 12 daylight hours. Assuming that an additional 25% of the total water used during the day is used at night, about 75 L a day of water are used per day per family, 10 times less than the amount used by the average Peruvian family with in-house water connections (1134 L) (Webb S. Waterborne disease in Peru. World Bank; August 1992, unpublished working paper).

In Canto Grande, water costs about $0.38 per 378 L. This price is nearly five times what it costs a family with in-house connections ($0.08 per 378 L). Both the *pueblo joven* and the middle-class families spend approximately 2% of their monthly income on water ($2.22/$120.00 and $7.2/$500.00, respectively). However, whereas *pueblo joven* families receive small quantities of poor quality water, middle-class families enjoy large quantities of relatively good quality water.

Mothers' attitudes and behavior on hygienic issues. Nearly all the 107 mothers surveyed in Las Pampas de San Juan were aware that hand washing and boiling of water were important methods of blocking the transmission of infection (Table 5). However, this knowledge did not affect the type of water that mothers reported drinking. Thirty-seven (35%) mothers said that a portion of the water they consumed was not boiled. Yet these mothers knew that boiling water killed germs as often as did the mothers who drank only boiled water. About 90% of mothers knew that contamination of hands with feces produced disease.

Discussion

This study used direct observation because it is the most accurate method for documenting family hygienic behavior.[13,21] The duration between fecal contamination events and their interruption by hand washing was analyzed using survival curves to analyze hygienic behaviors that are censored at varying times.

Water quantity has been considered an important factor in diarrheal disease prevention.[8] We found that families that used more total water interrupted fecal contamination by hand washing more often. Interruption of fecal contamination was not influenced by mother's education or by family socioeconomic characteristics.

In Bangladesh, where water is plentiful, sanitary education was effective in reducing the number of diarrheal episodes.[9,10] In Lima, where per capita levels of water are among the lowest reported,[22] the majority of *pueblo joven* mothers knew that fecally contaminated hands transmitted disease, yet few washed their hands after obvious fecal contamination. Although knowledge about sanitation practices was adequate, hygienic practices were poor, presumably because water is scarce.

In addition to being insufficient in quantity, the water is also lacking in quality since it is stored in easily contaminated uncovered or partially covered tanks or cylinders. The effect of contamination is somewhat mitigated since more than 85% of water is boiled before consumption.

However, based on the speed with which cholera spread through the *pueblo jovenes*, it would appear that the remaining 15% contamination is enough to effectively transmit disease.

In 1992, because of drought, water was more expensive and scarcer than it was in 1987 (personal communication, Dr Carmen Marin, AB PRISMA, Lima, Peru, July 10, 1993). During the 1992 cholera epidemic, there were widespread media messages about boiling water and washing hands. Yet in a 1992 study of water practices, the percentage of water not boiled before drinking and the number of episodes of fecal contamination not purposely interrupted were similar or slightly worse than what was found in our 1987 precholera study.

The detection of fecal coliforms is the standard routinely used to determine water quality.[15,22] Our data and others[17,22] suggest that counts of *Aeromonas* and *Vibrio* species may also be useful for monitoring the purity of drinking water. We and others found no association between coliform and *Aeromonas/Vibrio* counts.[17]

Lima's *pueblo jovenes* have one of the highest diarrheal rates reported: 10 episodes per year.[23] Our results suggest that providing increased information concerning hygiene without providing increased water probably will not result in better sanitation practices. In water-scarce communities, personal hygiene and possibly the number of diarrheal episodes would be improved by providing convenient, cheap, in-house water. For the same cost as they are paying now, in-house connections to a *pueblo joven* household would provide four to five times the volume of high-quality water as they are currently receiving. The money saved by reducing diarrheal episodes would eventually cover some or all of the installation costs. Costs can also be reduced if the community provides free labor and perhaps designs less orthodox and lower-cost systems.[24] In-house water connections would measurably improve the quality of life in the periurban marginal communities of Peru. □

Acknowledgments

Financial support for this research was provided by the RG-ER fund, Smith Kline French Co, and the US Agency for International Development, PSTC grant #7234. We thank Drs M. Bateman and J. Briscoe for their helpful comments concerning the manuscript; M. Rau Rau for able field support: and J. B. Phu, D. Sara, and M. Manuco for assistance. We also thank the communities of Huáscar, Bayovar, and Las Pampas de San Juan for their collaboration.

An Epidemic of Pesticide Poisoning in Nicaragua: Implications for Prevention in Developing Countries

Rob McConnell, MD, and Allan J. Hruska, MS

ABSTRACT

Objectives. The purpose of this study was to demonstrate the usefulness of the Northwestern Nicaraguan Ministry of Health surveillance system for detecting pesticide poisonings.

Methods. Cases were reported to the regional department of epidemiology through daily telephone reports and through monthly consolidated reports from each of the 18 health centers of the National Health Service. Reporting forms were also distributed to the four area hospitals.

Results. During June and July 1987, an epidemic of 548 pesticide poisonings was detected in northwestern Nicaragua. Seventy-seven percent of the poisonings were caused by carbofuran or methamidophos. Of the work-related cases (91% of reported poisonings), more than 80% occurred among maize farmers and on small to medium land holdings (fewer than 140 hectares). Nineteen percent of the work-related cases involved children under 16 years of age.

Conclusions. Unsafe working conditions such as manual application of pesticides and the use of backpack sprayers, the introduction of a hazardous powdered formulation of carbofuran highly restricted in the developed world, and agricultural subsidies that encouraged the use of hazardous pesticides all contributed to the epidemic. (*Am J Public Health.* 1993;83:1559–1562)

Introduction

Pesticide poisoning is a major public health problem in the Third World. Recent worldwide estimates suggest that each year, there are 3 million severe, acute pesticide poisonings and 220 000 deaths.[1] Most of the poisonings and 99% of the deaths are believed to occur in developing countries, although the Third World accounts for only 25% of total worldwide pesticide consumption.[2] Although food-borne outbreaks of severe poisoning, which often result in hospitalization, are reported commonly in the Third World,[3] there are remarkably few well-documented examples of epidemics of worker poisoning. Unfortunately, most available data in Latin America reflect hospital-based (severe) poisonings, because there seldom exists the capability to organize surveillance systems outside hospitals.

In the early 1980s, Nicaragua implemented a series of social reforms, including redistribution of agricultural land to small farmers, and universal health coverage was provided through the new unified National Health Service, which emphasized primary care services and preventive public health.[4] Surveillance systems for preventable diseases were established, including a regional pesticide poisoning registry for the 632 000 people living in the principal agricultural area on the northern Pacific Coastal plain.[5] Reporting forms were distributed to the four hospitals and the 18 health centers of the National Health Service, which was the exclusive source of medical care for most of the rural population in this region. The reporting of pesticide poisonings increased immediately (see Figure 1).

The usefulness of the system was demonstrated in an epidemic of poisonings in June and July 1987 (see Figure 2). Two peaks in frequency of poisoning occurred in two distinct seasons: June and July, corresponding to the planting of food crops (especially maize), and September through December, corresponding to the cultivation of cotton. However, the number of poisonings involving food crops increased disproportionately in 1987. Information collected through the surveillance system made it possible to identify and characterize the epidemic.

Methods

Cases were reported to the regional department of epidemiology through daily telephone reports and through monthly consolidated reports of all reportable diseases from each health center of the National Health Service. Name, age, location where poisoning occurred, reporting center, and (sometimes) job title and pesticide used were available through these reports. These reports were used to direct the regional ministry's outbreak control unit, which conducted investigations and on-site worker training in safe use of pesticides and screened workers for cholinesterase depression (a test for subclinical overexposure to toxic organophosphate insecticides). The regional department of epidemiology also provided follow-up cholinesterase tests for overexposed or poisoned workers referred by the health centers. Treating clinicians were almost exclusively physicians who had been trained in the diagnosis and treatment of acute poisoning in a course run by

TABLE 1—Principal Pesticides Responsible for Occupational Poisonings: June–July 1986 and June–July 1987

Pesticide	Total Cases, %		Change in No. of Reported Poisonings, 1986–1987	Proportionate Morbidity Ratio Based on 1986 Standard (95% Confidence Interval)[14]
	1986 (n = 181)	1987 (n = 351)		
Carbofuran	26	46	+131	173 (159, 186)
Methamidophos	39	31	+39	80 (73, 88)
Chlorpyrifos	13	6	−5	40 (32, 51)
Methyl parathion	...	2	...	... ...

Note. Reports with missing data are not included.

the Ministry of Health. A summary of descriptive statistics from the registry was distributed quarterly to each clinic in the region. Field observations of pesticide applications were made during the period of the epidemic.

Results

The epidemic of June and July 1987 was not the result of improved reporting, because the increase was confined to this 2-month period (Figure 2). Of the 548 cases reported (316 in June and 232 in July), 91% (368/404) were occupational, 8% involved other accidents, and 1% were suicide attempts. (Of the 548 responses to the question regarding type of poisoning (occupational or otherwise), 144 (26%) were left blank by the reporting health workers. In general, missing data were not included in the calculations presented.) The description of the epidemic is restricted to occupational poisonings. Of the four deaths, three were suicides and one was a nonoccupational accident. Three of the four deaths were caused by the insecticide methamidophos.

Of the occupationally exposed patients for whom sex was reported, 96% (353 of 368) were male. The mean age was 27 years, and 19% (71 of 366) of the patients were less than 16 years old, the minimum legally permissible age for working with pesticides in Nicaragua.[6] Forty-one percent (166 of 404) of occupational poisonings were relatively more severe occurrences reported from hospitals. Eighty-six percent (301 of 351) of the cases for which crop was indicated involved maize. Eighty-two percent (276 of 338) of the poisonings for which size of farm was identified occurred among workers on small and medium-sized farms (fewer than 140 hectares). Only 10% (35 of 338) and 8% (27 of 338) occurred among workers on large private farms and state farms (greater than 140 hectares), respectively.

The insecticides responsible for the epidemic were cholinesterase inhibitors. More than half of the poisonings involved a carbamate insecticide, and almost half involved an organophosphate. Two specific insecticides were most often implicated (see Table 1). Almost half of the poisonings involved the carbamate insecticide carbofuran (sold under the trade name Furadan), which at the time was imported from Mexico, and one third resulted from the organophosphate methamidophos, a peripheral neurotoxin[7] (sold in Nicaragua as Monitor, Filitox, Tamaron, and MTD). The increase in carbo-

furan poisonings from 1986 to 1987 accounted for the majority of the overall increase (in occupational poisonings for which the responsible pesticide was reported by the health worker). Thirty percent of the carbofuran poisonings for which the type of formulation was indicated reportedly involved powder, a formulation that is severely restricted in most of the developed world because of the easy absorbance by the respiratory tract. Most of the remainder of the absolute increase was accounted for by methamidophos, although the proportion of all poisonings caused by methamidophos decreased. Of note is that the number of poisonings involving chlorpyrifos decreased.

Discussion

The epidemic demonstrates the viability of a clinic-based comprehensive surveillance system in the Third World and the value of this system in detecting, measuring, and, ultimately, alleviating outbreaks of pesticide poisoning. Contrary to the common conception that clinic-based surveillance is difficult in the Third World, the surveillance system functioned effectively because participating clinicians perceived the benefits that the clinics received from reporting: an outbreak control unit that responded to clinicians' requests, a training course designed to upgrade clinical skills in the treatment of pesticide poisoning, a referral center for follow-up of poisoned workers, and periodic feedback on patterns of pesticide poisoning in the region. The system could be implemented because rural access to health care was almost universal under Nicaragua's National Health Service.

Surveillance is a powerful tool for demonstrating the public health impact of pesticides in a way that impresses the public. Based on a crude estimate that two thirds of poisonings are not reported, 3602 cases of medically treated poisoning may have occurred in this region in 1987 (or 5.9/1000, based on 1234 reported cases for the year and a total population of 632 000). (A survey of 633 agricultural workers identified 24 who reported that they had been treated for poisoning.[8] Only 8 of these cases were actually reported to the surveillance system.) Further review of data on childhood poisoning in this region revealed an alarming increase in the proportion (as well as in the absolute number) of reported poisonings among children, from 12.7% of all poisonings in 1984 to 17.1% in 1987 ($\chi^2 = 3.24$, for slope; $P = .072$).[9] During the mid-1980s, young men who traditionally applied pesticides were away at war. Because pesticide application is not a job that requires extensive physical strength and because of the shortage of adult labor, children were used in this activity.

Health authorities declared a regional health emergency 3 weeks into the epidemic, a media campaign was begun to advise workers in less hazardous handling of carbofuran, and outbreak control and preventive education were expanded through the clinic network. Proposals emerged to substitute less hazardous imports for more hazardous ones, and there has been no repetition of the dumping of carbofuran powder on the Nicaraguan market.

However, the long-term impact of the epidemic in reducing pesticide poisoning in Nicaragua, as well as the ability of the health sector, by itself, to reduce poisoning in the Third World in general, is questionable. The reason is that the health sector can offer little more to workers than health education and the promotion of personal protective equipment as a solution to the problem of endemic pesticide poisoning, a solution actively promoted by the pesticide industry.[10] The reasons for pesticide poisoning in the Third World (and for this epidemic) often include economic factors outside of the control of the health care system. For example, health effects are seldom considered anywhere in the Third World in developing policy on pesticide subsidies, although subsidies that encourage pesticide use are common.[11] During 1987, pesticides were supplied almost free of charge to most Nicaraguan farmers through favorable exchange rates and negative real interest rates.[12,13] As a result of subsidies, farmers increased the number of applications in maize, the crop involved in most of the poisonings, from 4.2 to 6.3 per season. In addition, in 1987, the price at which maize could be sold was deregulated by the government from its previously fixed price. Production of maize increased in the region from 12.1 million kg to 49.1 million kg between 1986 and 1987 (unpublished data, Ministry of Agricultural Development and Agrarian Reform 1988), and demand increased for highly toxic carbofuran and methamidophos for control of maize pests. The weight of imported carbofuran active ingredients increased by more than 50% from 1986 to 1987. In addition, importation of chlorpyrifos ceased, in part because chlorpyrifos was more expensive than either methamidophos or carbofuran. Since there was a shortage of chlorpyrifos, which is considerably less acutely toxic than carbofuran, workers substituted carbofuran for chlorpyrifos.

Working conditions typical of the developing world contributed to the epidemic. In the developed world, carbofuran granules are applied by tractor, entailing little exposure to the applicator. In Nicaragua, carbofuran was mixed with urea, which facilitated dermal absorption, and applied by hand. As noted above, carbofuran also was available in a powder formulation in 1987. In the developed world, acutely toxic liquid pesticides such as methamidophos are applied by planes or tractor-drawn boom sprayers. Among small farmers in the developing world, they are applied by backpack sprayers, and leakage is common. Most occupational pesticide poisonings in this region occur during backpack application. In addition, most farmers received no training in the hazards of pesticides because there were essentially no agricultural extension services such as those in developed countries, and protective rubber gloves and respirators, had they been available, cannot be worn by farmers working in the tropical sun in a humid climate where ambient temperatures reach 40°C. Finally, like most Third World countries, Nicaragua still does not require that imported pesticides be registered in the country of origin, and pesticides banned or restricted in the country of origin are used widely.

This epidemic suggests that the importation of acutely toxic pesticides, pesticide subsidies, and the overuse of pesticides under primitive working conditions are major causes of poisoning in developing countries. The number of poisonings decreased only slightly in 1988, the year after the well-publicized epidemic (see Figure 1). A further decline in 1990 probably resulted from markedly reduced subsidies for pesticides purchased by small farmers (although it may reflect greater underreporting as a result of decreased funding for health). Although surveillance is necessary to focus attention on the problem of pesticide poisoning, recent experience in reducing pesticide use suggests that policies promoting nonchemical alternatives to pest control may be the most appropriate solution to the problem of poisoning in Nicaragua and elsewhere in the Third World.[15] □

Acknowledgments

Dr Feliciano Pacheco Anton, chief of occupational health for the Nicaraguan Ministry of

Health in Region II, established the poisoning surveillance system in 1984 and has since promoted its use. Without his work, this epidemic would have gone unnoticed. The surveillance system also was supported by the Nicaraguan Ministry of Health (Region II), CARE Nicaragua, and the American Friends Service Committee.

This work was presented at the 117th Annual Meeting of the American Public Health Association, October 1989, Chicago, Ill.

We appreciate the assistance of Fresia Morales Cabrera and the thoughtful comments of Dr Douglas L. Murray.

Fatal Occupational Injury Rates: Quebec, 1981 through 1988

ABSTRACT

Objectives. The purpose of the study was to estimate the death rates from occupational injuries in the province of Quebec for the period 1981 through 1988.

Methods. Worker's compensation files were used to ascertain numbers of deaths, which were used as the numerators in figuring the rates (it was estimated that these files reported 83% of the true number of deaths among men). Annual average estimates of the labor force were used as denominators.

Results. From 1981 through 1988, compensation was awarded for 1227 fatal work injuries. Among men (96% of the victims), rates declined from 1981 to 1988 (from 12.7 to 8.1 per 100 000); women's rates were stable (≤1.0 per 100 000). Compared with men, women had excess mortality from violent acts. Motor vehicle crashes accounted for 36% of all fatal injuries in 1984 and 1985 and declined thereafter. Fatal injury rates in forestry and mining rose to a 1987 maximum of 67.6 per 100 000. The construction sector had the largest number of deaths, despite a decline in rates from 1981 to 1988 (from 27.8 to 15.9 per 100 000).

Conclusions. Except for construction and agriculture, reported fatal occupational injury rates in Quebec were similar to those in the United States. Motor vehicle crashes, falls, violent acts, and farming-related injuries were the most frequent causes of death. (*Am J Public Health.* 1993;83: 1563–1566)

Michel Rossignol, MD, MSc, and Marc Pineault, BSc

Introduction

Comparison of fatal occupational injury rates is difficult, largely because of differences in definitions and methods for estimating the numerators and denominators of these rates. The discrepancies between some of the rates reported for the United States suggest that case ascertainment remains an important limitation in our understanding of fatal occupational injuries. The National Safety Council, the Bureau of Labor Statistics, Bell et al., and Baker et al. reported, respectively, annual crude rates of 13, 7, and 9.1 (1980) and 7 (1978) per 100 000.[1–4]

The objective of this study was to estimate the death rates from occupational injuries in the Province of Quebec for the period 1981 through 1988 by sex, age, and industrial sector.

Methods

Numerators

In Quebec, any person who hires another to do a job for a salary or other form of benefit must register with the Quebec Worker's Compensation Board to insure the employee in case of occupational injury or disease. Most employees in Quebec, with the exception of employees under federal administration, military personnel, and most of the self-employed, are covered under this scheme. For use as the numerator of death rates in this study, we counted all cases in which compensation was paid to the relatives of a worker, aged 15 years or older, who died from unintentional or intentional injuries (except suicide) sustained while working or at the work site from January 1, 1981, through December 31, 1988.

Reporting to the Quebec Worker's Compensation Board protects the employer against lawsuits in the compensation system. Fatal injuries were determined by the Board to be occupational if the victim was pursuing a gainful activity at the time of the event or the injuries were inflicted on the employer's premises (including parking lots). Deaths from occupational diseases and exertional heart attacks, which are sometimes coded as occupational injuries by the Board, were excluded from this study.

Denominators

The annual average labor force estimates of Statistics Canada for Quebec, 1981 through 1988, were used as denominators.[5] These averages were based on monthly interview surveys of families randomly selected to be representative of the population of Quebec (response rates over 95%). Excluded from these estimates were persons younger than 15 years of age, full-time military personnel, most inhabitants of Indian reserves, and institutionalized persons. Statistics Canada provided estimates of the sampling error in the form of standard deviations for the number of employed persons by age, sex, and industrial sector. In this study, we used data on industrial sector only for 1984 and following years, because the classification system used before 1984 was not compatible with the current one.

Services (98%)	2.5 (9)	4.2 (16)	2.4 (9)	4.8 (18)	5.3 (21)
Missing	1	1	3	1	1

Note. In calculating these rates, the numerator was taken from Quebec Worker's Compensation Board figures; the denominator was taken from Statistics Canada annual averages of the employed population. The Canadian classification of industrial sectors based on the 1981 revision was first used in 1984.
[a]Compensation coverages reported elsewhere.[8]
[b]Primary sector other than agriculture: fishing, forestry, and mining.
[c]Utilities include gas and electricity.
[d]Provincial and municipal, including protection and police services.

Statistical Analysis

Death rates were computed for each year from 1981 through 1988 by age and sex, and from 1984 through 1988 by industrial sector. Age and sex standardization of the rates was performed with the 1981 population structure as the reference.[6] The adjusted rates were almost identical to the crude rates; therefore, the unadjusted rates are presented throughout this report. Years of potential life lost were computed for each death by calculating the difference between the age at death and 65.[7]

Measure of Error

Confidence intervals (95%) were computed for each rate, based on the Poisson distribution and taking into account the sampling error of the denominator provided by Statistics Canada.[5] To account in part for the exclusion of the self-employed from the compensation system data (numerator), compensation coverages had been previously calculated by age, sex, and industrial sector from a combination of compensation files and coroner's death certificates for the years 1987 and 1988.[8] It was estimated that the compensation coverage of fatal occupational injuries was 83% for men and 100% for women. Compensation coverages are reported throughout this paper for greater accuracy in interpreting the rates.

Results

From 1981 through 1988, the Board compensated 1227 fatal injuries. Rates among men (96% of the total) declined from 1981 (12.7 per 100 000; 95% confidence interval [CI] = 11.1, 14.6) to 1984 (8.2 per 100 000; 95% CI = 6.9, 9.8) and remained stable thereafter. Because compensated cases represented roughly 83% of the true number of deaths among men, the rates would actually be closer to 15.3 (1981) and 9.9 (1984) per 100 000.[8] Among women, rates ranged from 0.2 to 0.8 per 100 000; 53% of the fatal injuries were related to motor vehicle crashes. Although they represented only 4% (n = 47) of all fatal injuries, women were victims of 14% of the fatal violent acts that occurred during the period studied.

Motor vehicle crashes accounted for 25% (n = 54) of all occupational injury deaths in 1981, increasing to 36% in 1984 (n = 49) and 1985 (n = 52) and dropping thereafter to a low of 21% (n = 30) in 1988. Two causes of fatal injuries showed regular increases in proportion between 1981 and 1988: falls to a lower level (an increase from 8% to 15%) and electrocutions (an increase from 4% to 6%) (chi-square; $p < 0.01$).

Fatal occupational injury rates increased with age, reaching 11.4 per 100 000 in the group aged 55 years and older (Table 1). The lower compensation coverage in that age group (66%) would bring the rate to 17.3 per 100 000. It was also these workers who showed the most dramatic drop (53%) in rates between 1981 (15.6 per 100 000) and 1988 (7.4 per 100 000). Fatal injuries in the older age group were associated in higher proportions with "being struck by" objects (27%) and with falls (17%). The 35- through 44-year-olds had the highest proportion of motor vehicle crash–related fatalities (38%). In terms of years of productive life lost, the 25- through 34-year-old age group came first, with a total of 11 337, followed by the 35- through 44-year-old group (6847) and the group aged 20 through 24 years (5481).

The only industrial sector that showed a regular increase in fatal injury rates, and also the one with the highest rates, was the primary sector (fishing, mining, and forestry) (Table 2). The rates in this sector peaked in 1987 at 67.6 per 100 000, nearly a fourfold increase over 1984 rates. This increase was explained by an increase in fatal injuries in the forestry industry, in which the number of deaths rose from 8 in 1984 to 25 in 1987 and 19 in 1988.

The construction sector, on the other hand, showed a steady 43% decrease between the years 1984 and 1988. It had the

highest number of deaths (119, or 18% of the total from 1984 through 1988) and the largest proportions of deaths from falls (30%) and electrocutions (10%). Transportation, communications, and public utilities were second for number of deaths (113 deaths, or 17% of the total from 1984 through 1988), almost half of which (46%) were related to motor vehicle crashes. Considering the low compensation coverage in this sector (77%), this sector would account for the largest number of deaths, and rates would be closer to 16.2 (1984) and 18.8 (1987) per 100 000.

Agricultural death rates were low, but because of the low compensation coverage (46%), the true rates would be twice those shown in Table 2.

Discussion

Information on cases of occupational fatal injuries is often incomplete in the United States, where differences of up to 300% have been found in rates reported by different sources of information.[9] Death certificates have been the information source of choice because more deaths could be identified from death certificates than from surveys or inspection reports.[10] The Quebec Worker's Compensation Board information system on fatal occupational injuries was found to provide more accurate information than death certificates in Quebec except for older workers and those in transportation and agriculture, where compensation coverages were found to be low.[8]

The specification of sex when reporting fatal occupational injury rates is a point that deserves special attention. Because men accounted for 96% of all fatal injuries but for only 60% of the work force in Quebec, the rates for both sexes combined underestimate the real situation for men almost by half. For example, our men's rate for the year 1988 was 8.1 per 100 000, but the rate for both sexes combined was only 4.8 per 100 000. The National Safety Council's work-related accidental death rates did not mention sex, so it is assumed that both sexes were combined in the Council's estimations by year and industry.[1] For any comparison with these rates to be fair, one must multiply the denominator of the rate by the proportion of men in the working population. If the proportion of men in the US work force is 60%, as it is in Quebec, the 1988 death rate for men in the United States would be not 9 per 100 000, the rate reported by the National Security Council, but 15 per 100 000, which is almost twice as high as the rate of 8.1 we found for men in Quebec.

In two different studies, homicides accounted for 53%[11] and 39%[3] of women's fatal occupational injuries. These proportions are difficult to compare with ours (17%) because our data included only 47 deaths among women. Nevertheless, there is enough consistency to justify specific prevention programs aimed at protecting women who are in direct contact with the public.

In the 8 years prior to 1981, a 35% decrease in death rates from occupational injuries was reported for Quebec.[12] The secular downward evolution could be partially explained by the gradual introduction of safer working conditions and practices. However, this pattern was not sustained through the 1980s with rates that remained stable after 1983. After 1983, for instance, the 50% reduction in fatal injury rates in the construction sector was counterbalanced by a threefold increase in the primary sector. The large contribution of forestry to this increase was similar to what was reported in British Columbia.[13]

The rising proportion of motor vehicle crashes as occupational fatalities is a concern that Baker et al.[4] pointed out more than 10 years ago when they urged the need for preventive measures addressed to professional drivers. Little has been achieved in Quebec to improve the situation. The rate of truck crashes (of trucks weighing more than 4.5 metric tons) causing any type of injuries increased from 18.0 per 1000 vehicles in 1982 to 22.8 in 1986, and for each death of a truck occupant, 4.6 additional deaths occurred among nonoccupants.[14] The increasing weight and length and number of trailers pulled have been implicated as factors influencing crash involvement.[15] Three sectors accounted for 62% of all fatal motor vehicle crashes: transportation, wholesale and retail, and services. Energetic action must be taken to address this No. 1 occupational cause of death.

Another important finding was the higher fatal injury rates among workers aged 55 and older. The pattern was more pronounced than that reported by Baker et al.[4] Falls caused more deaths among these workers than in any other age group, and the proportion of deaths due to falls increased between the years 1981 and 1988. Factors that influence older persons' stability and balance, including antihypertensive and antihypoglycemic drugs, could be of importance in the workplace. Such a hypothesis deserves further attention.

Between 1981 and 1988, 19 fatal injuries were compensated in the farming sector. The compensation coverage rate of only 15% would bring the actual number of deaths to around 146, second only to motor transport operation (for which there were 202 compensated, or 264 estimated, deaths). Our rates for agriculture cannot be compared directly with those reported in the United States, where fishing and forestry are included in the agricultural sector. In addition, gross errors in estimating the number of deaths in agriculture have been reported.[16,17]

In Quebec, as in the United States, half of the fatal injuries in farming were related to farm tractors.[4,15] Goodman et al. estimated the annual tractor-related fatality rate for males to be 23.6 per 100 000 male farm residents in the state of Georgia for the years 1971 through 1981.[18] This figure is almost as high as our highest estimation of the death rate in the agricultural sector (28.7 per 100 000). The application of rollover protection structures in farm tractors has been examined by Kelsey et al.[19] and Karlson et al.[20] This hazard has remained largely unrecognized in Quebec because of an insufficiency of data outside the compensation statistics. The public health authorities must be alerted to the seriousness of the situation so that they can formulate new priorities for the agricultural sector. □

Modern Contraception Use in Ethiopia: Does Involving Husbands Make a Difference?

Almaz Terefe, BSc, MPH, and Charles P. Larson, MD, MSc, FRCPC

ABSTRACT

Objectives. This study was undertaken to determine the relative efficacy of home visitation with and without husband participation on the use of modern contraception in Ethiopia.

Methods. A randomized field trial of a family planning education intervention using home visitation with and without husband participation was conducted in Addis Ababa, Ethiopia, from August 1990 to December 1991 and included a 12-month postintervention follow-up. A total of 266 experimental and 261 control subjects were entered, of whom 91.7% and 88.9%, respectively, were followed through 12 months.

Results. A greater proportion of couples in the experimental group were practicing modern contraception at 2 months (25% vs 15%) and 12 months (33% vs 17%) following the home visit intervention. By 12 months following the home visits, experimental subjects were less likely to have defaulted and more likely to have started using modern contraception following an initial delay.

Conclusions. The inclusion of husbands in family planning programs will result in relevant increases in the use of modern contraception. However, there exists an important "sleeper" effect to the education intervention, reflected by a delay of greater than 2 months in the initiation of modern contraception for most couples. (*Am J Public Health.* 1993; 83:1567–1571)

Introduction

Rapid population growth, which in many instances far outstrips economic growth and environmental sustainability, is the reality in most developing countries of sub-Saharan Africa.[1–3] Within this region, annual population growth rates over the past 2 decades have continued to increase, and the contraception prevalence rate has remained under 10%.[1,2]

In Ethiopia the overall contraception prevalence rate among women of childbearing age (15 to 49 years) is less than 2%, and the crude birth rate is estimated to be 49 per 1000 population.[1] Most women in Ethiopia marry by the age of 15, and less than 6% remain single by the age of 24.[4] On average, Ethiopian wives experience seven pregnancies during their lifetime, each pregnancy carrying about a 1% risk of death.[1,3,5,6] These figures are associated with an annual rate of population growth of approximately 3%.[1,2] Applying the lower end of national fertility projections, the current Ethiopian population of 50 million is expected to reach 90 million by 2010 and 165 million by 2035.

The aim of the program was to initiate and sustain modern contraceptive use among married couples. Because the limited research on male roles in Ethiopia and sub-Saharan Africa has consistently found that decisions regarding family size and contraception are dominated by husbands, who expect to have large families,[7–12] this field trial was undertaken to determine what effect involving husbands in a community-based, home visitation, health education program would have on the use of modern contraception in Ethiopia.

Methods

Study Design

This was an experimental, randomized field trial comparing the relative effectiveness of a modern contraception educational intervention program in Ethiopia with and without husband participation. The general architecture of the study and enrollment are found in Figure 1. The interventions were carried out between August 1990 and January 1991, and modern contraceptive use was verified at 2 and 12 months following intervention.

The study was conducted in the semi-urban, peripheral Kotebe District, one of 18 districts in Addis Ababa. Kotebe is located at about 12 kilometers northeast of the city center. Approximately 80% of its population of 43 000 is urban. The source population for the field trial was any urban Kotebe female resident between the ages of 15 and 49 years who was married and living with her husband. It was estimated that there were approximately 1214 women eligible for this study residing within the 12 randomly selected zones. Excluded from eligibility were women currently using modern contraception, pregnant women, and women with a chronic physical or mental illness. Prior to this study, no family planning outreach program was or had been in existence.

Local, trained traditional birth attendants who were currently working in the district and had, on average, more than 10 years experience in the community were paired with a female interviewer having a 12th-grade education. The pairs were pro-

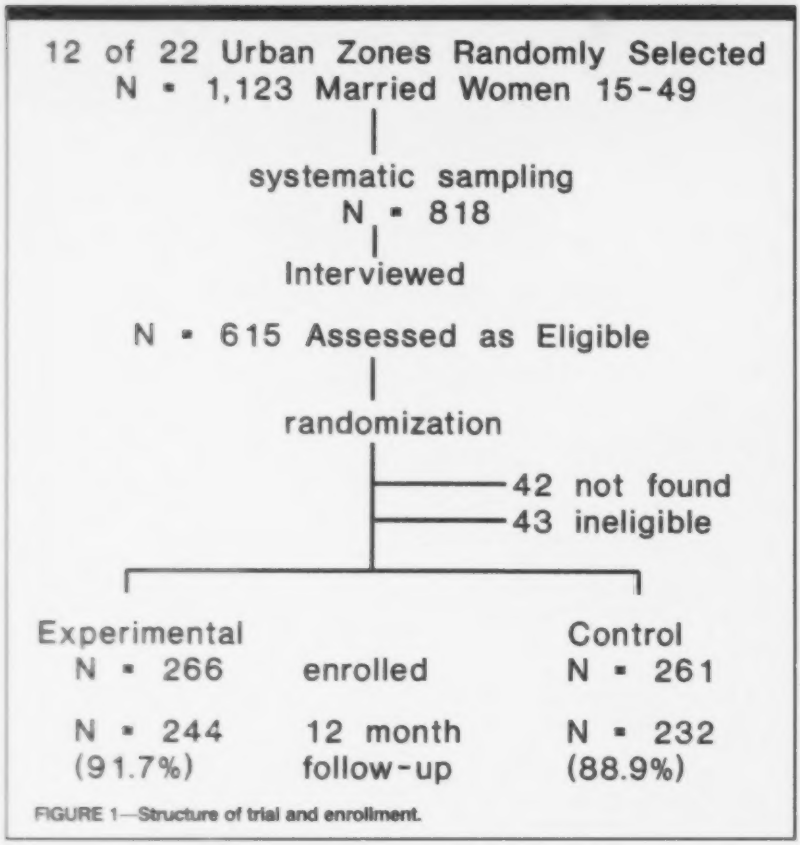

FIGURE 1—Structure of trial and enrollment.

vided with the names of married women of childbearing age who resided in their respective zones and were systematically selected on a 2:1 basis from a census list. The birth attendants identified these women, confirmed their eligibility for enrollment (203 of 818 were excluded), and arranged a date and time for a home visit. The interviewer completed a baseline questionnaire, which in all instances, was conducted with the wife only. The interviewers were unaware of the research objectives and group assignments. Following completion of the questionnaire, one of the principal investigators (AT) collected blocks of eight names and assigned them as control or experimental subjects based on random assignment schedules for each home visitor. At the time of the follow-up home visit, a further 88 subjects were excluded: 42 had moved or could not be found, 43 were ineligible (24 were pregnant, 13 postmenopausal, 6 on contraception), and 3 had husbands who refused the visit. The final enrollment figures were 261 control and 266 experimental subjects. There was no loss of subjects at the 2-month follow-up, but 29 control (11.1%) and 22 experimental (8.3%) subjects were lost to follow-up after 12 months.

Intervention

Eight female health assistants, accompanied by the traditional birth attendants involved in the initial contact, conducted the home visits. These health assistants were employed at the local district health station and were known to the community. They worked on this project in the early evenings and on weekends, which facilitated scheduling the husbands in the experimental group. The health assistants were trained to maintain an informal atmosphere and to permit spontaneous communication.

After briefly explaining the purpose of the study, the health assistants requested the consent of the participants. Next, they provided health education on family planning and modern contraceptive methods to either the wife alone (control group) or the wife and husband (experimental group). (The eight health assistants had an almost equal number of control and experimental subjects.) The sessions generally started with a discussion of the health of the family, which is a culturally acceptable manner in which to initiate a conversation. Questions on the woman's reproductive history were then used as the entry point into the actual family planning education. The content of the education focused on the advantages of family planning as a means of preventing unwanted pregnancy and birth, of spacing births, and of controlling family size. Health assistants discussed the advantages of birth spacing for the mother, children, and family with respect to both promotive and preventive aspects of health. Additionally they stressed the ill effects of a large family on all family members and on the nation as a whole. This was followed by an explanation of alternative contraceptive methods—the birth control pill, the intrauterine device (IUD), and the condom—and a discussion of the relative efficacy of modern contraception versus traditional methods.

A maximum of two visits were made. Couples intending to initiate modern contraception were allowed their choice of method and provided with the appropriate explanations and information about follow-up. The contraceptive method was provided at the conclusion of the home visit, if requested. This included either two cycles of birth control pills, two dozen condoms, or a copper-T IUD set to be brought to the local health center for insertion.

The hypothesis to be tested was as follows: those couples in which husband and wife receive family planning education in the home will have a significantly higher rate of modern contraceptive use at 2 and 12 months following the intervention than those couples in which the wife alone receives such education ($P < .05$, two-sided).

Measurement

Baseline sociodemographic and reproductive histories as well as knowledge about and attitudes toward modern contraception were obtained prior to randomized assignment and a home visit. Initiation of contraception was recorded as yes on the basis of stated intent following the home visit. At 2 and 12 months, the use of modern contraception was verified on the basis of current birth control pill use and refills, condom refills, or proof of IUD insertion. In all instances, this information was obtained from the wife.

Analysis

All questionnaires were checked by one of the principal investigators for accuracy, and the data were coded. Data were entered, edited, and analyzed using EPI-INFO version 5.01B (USD, Inc., Stone Mountain, Ga).

Results

Ninety-five percent of the study group were Orthodox Christians, and 85%

of the women were housewives. The language of origin in two thirds of the participants was Amharic while that of the rest was mostly Oromigna. Two thirds of the husbands were government employees, which includes local factory workers. There were no between-group differences in these characteristics. Complete follow-up through 12 months was achieved in 91.7% of the experimental and 88.9% of the control subjects.

Table 1 summarizes the between-group comparison of demographic and reproductive histories. There were no significant differences between control and experimental subjects found at enrollment, except that control group women had a slightly higher number of siblings ($P < .05$). The level of education of 70% of the women was 6th grade or below, while 70% of the men had completed 5th grade or higher. Husbands in this study were also older than their wives. The number of women having one to two children, three to four children, and five or more children ranged between 25% and 30% for each category and was evenly and uniformly distributed across both groups. Only 6.6% of the women had no living children.

There were no significant group differences in family planning knowledge or attitudes. The majority of the women (65%) wished to have four children. Fifteen percent of the women had not heard of modern contraceptive methods while about 40% knew of only one such method: mainly the birth control pill. Husbands were generally supportive of the need for family planning (57% and 69% in control and experimental subjects, respectively).

Following the home visit intervention, 47.0% (n = 125) of the experimental versus 33.0% (n = 86) of the control women decided to start using modern contraception (relative risk [RR] = 1.42, 95% confidence interval [CI] = 1.15, 1.76). In more than 90% of cases, the birth control pill was chosen. At 2 months following the home visit intervention, it was confirmed that approximately one-half of all couples who had stated their intention to initiate modern contraception were not using it. The practice of contraception at 2 months was verified in only 24.7% (n = 66) experimental and 15.3% (n = 40) control subjects (RR = 1.61, 95% CI = 1.13, 2.30). This analysis was further stratified by the presence or absence of husband support for family planning. Relative risk estimates and 95% confidence intervals remained above 1 and favored the experimental subjects with and without husband support. No significant interaction was found (Woolf's χ^2 0.14, $P = .71$).

Table 2 summarizes the modern contraceptive practices of those subjects who were successfully followed through 12 months after home visitation. From these figures, one can subgroup subjects into those who practiced modern contraception throughout the year (yes at 2 and 12 months), those who defaulted by 12 months (yes at 2, no at 12 months), those who delayed starting (no at 2, yes at 12 months), and those who never used it (no at 2 and 12 months). Experimental subjects were less likely to have defaulted from modern contraceptive use by 12 months (RR = 0.55, 95% CI = 0.37, 0.81) and more likely to have delayed starting it (RR = 1.58, 95% CI = 1.01, 2.46). At 12 months, twice as many experimental couples were using modern contraception as were control subjects (RR = 1.90, 95% CI = 1.36, 2.66). Overall, 25.2% of couples were using it at 12 months, and the majority of these (55.8%) initiated the practice 2 or more months after the home visit intervention.

Discussion

This randomized field trial of family planning education in the home with or without husband participation has demonstrated that, as hypothesized, providing a family planning educational intervention program in the home to the husband and wife significantly improves modern contraception use up to 12 months following the intervention. Usage as measured by early or late initiation, overall use at 12 months, and default rates was better in all instances among couples with husband participation than among those couples without husband participation. Given the favorable quality of the randomization, it is concluded that the differences can be attributed to husband involvement in the intervention program and have not been confounded by demographic, reproductive, or knowledge and attitude disparities between the two study groups.

Several investigators have found that Ethiopian and East African husbands expect to have large families and thus play a dominant role in a couple's decision to initiate modern contraception.[7-12] Given that most Ethiopian women will not initiate contraception without their husband's knowledge, a husband's disap-

proval can be expected to be a major deterrent to use. Unfortunately, favorable husband attitudes do not appear to be sufficient. For example, among the couples enrolled in this study, none of whom were practicing modern contraception at the outset, more than 60% of husbands supported the need for family planning. This high baseline level of husband support for family planning was unexpected and may explain the generally successful response to the two interventions. It may be that the husbands were providing the expected answer out of respect for the interviewer. Similar unpublished findings of high support but low practice have been found in the north-central Ethiopian district of Yifatna Timuga. While husbands may acknowledge the need for family planning, practice tends to be influenced by the high levels of misinformation regarding the side effects of modern contraception, particularly oral contraceptives.[7] This includes fears of sterility, arthritis, loss of weight or strength, and skin changes.

Of particular interest is the finding that most of the women initiated modern contraceptive use more than 2 months following the intervention. This delayed or "sleeper" effect was first described 40 years ago by Hovland and Weiss,[13] who attributed the delay in communication effect to the low credibility of the source of information. Over time, the inhibiting influence of the source diminishes and the message leads to change. It has been assumed, but unconfirmed, that health assistants and trained traditional birth attendants enjoy a relatively high status in Ethiopian communities; this may not be the case. Alternatively, the delays observed may be explained in terms of the time required to undergo a change in attitude and the degree of personal commitment required. Given that the use of modern contraception is contrary to past practices and familial expectations, the home visit may have shifted couples from a position of uncertainty or ambivalence to one of an acknowledged, positive desire to initiate modern contraception. Such a change in attitude and, subsequently, in actual practice is a process that, in a large subset of couples, may unfold over several weeks. The delays identified in this study suggest that family planning intervention programs should interpret early results cautiously.

Is the intervention package offered in this trial applicable to and realistic for other Ethiopian and sub-Saharan communities? To answer this question, three elements of the intervention require consideration: home visitation, the visitor, and the educational content. Home visiting is a labor-intensive activity that requires competent organizational skills at the district level and reliable transportation facilities. A maximum of two visits—and in most cases, only one visit—was provided. Four to six women or couples were seen in a half-day schedule. The equivalent of one full-time health assistant can be expected to serve from 1500 to 2000 couples per year in an urban community. In a rural setting, these numbers would be reduced owing to travel time. The large majority of the couples visited were not regular health institution attenders and, in the absence of home visiting, were unlikely to have benefited from an institution-based program. Without a community outreach component such as home visitation, family planning services would miss the large majority of their target population.

In this study, husband participation was high. Although there were a few instances in which the husband refused to complete the health education session, the vast majority were tolerant and available as scheduled. Several factors may explain this high rate of husband compliance. First, the visits were carried out by health workers well known to the community. These workers shared a common cultural and social background with the couples they visited and were aware of how to approach husbands in an acceptable and appropriate manner. Second, the educational message was ordered to respond first of all to the couples' main concerns or perceived barriers to use. Third, at the time this intervention was carried out, the stability of the government was very much in question. Thus, for security reasons, people tended to return home and stay at home after working hours. This situation probably facilitated the task of scheduling husband participation.

The interventions were provided by health assistants and trained traditional birth attendants who were currently working in the district following a brief period of training. This level of health professional is found throughout Ethiopia and most of Africa. The content of the intervention was based on the educational outline described; as mentioned, however, this content was modified according to the couple's family planning knowledge and attitudes, with which the birth attendants and health assistants were familiar. Given appropriate supervision and integration into existing health services, the interventions provided are considered applicable to any urban and probably most rural settings in Ethiopia.

At 12 months following the intervention, nearly one quarter of all subjects were using some form of modern contraception. In a district where the baseline contraception prevalence rate was 2%, the rise to 17%, even without husband involvement, is a strong endorsement of home visitation. With the inclusion of husbands, the program's impact on the use of modern contraception nearly doubled. If these results can be repeated in other settings, the benefits would seem to justify the personnel inputs. The training and supervision requirements are modest and applicable to districts where a health management system is in place and functional. Based on the study's findings, the development and evaluation of alternative models of home visitation and husband involvement that include evaluation of the intervention elements and costs in relation to its benefits is recommended.

This investigation does not take into account the interaction of multiple factors influencing the desire to have children—in particular, cultural factors that can vary widely between regions, districts, and even communities. Warwick[14] and others have cautioned against grand conclusions based on single studies, and we concur. Involvement of husbands must be linked to local realities and responsive to the expressed desires of communities. The intervention described in this study was developed following extensive consultation with the community and the national family planning program. Furthermore, we used existing resources and housed the program within the local health institutions. This provides, at best, a broad framework upon which to design similar family planning programs that involve men in contraception and constructively expand their family planning responsibilities. □

1994 National Committee for Clinical Laboratory Standards Annual Meeting

The theme of the 1994 National Committee for Clinical Laboratory Standards (NCCLS) annual meeting, "A View From the Bridge: Pressures on Laboratory Practice," takes a step back to observe clinical laboratory practice from different points of view. The meeting will be held at the San Diego Princess Resort, San Diego, Calif, March 24 through 26, 1994; it will provide an opportunity for constituencies from government, industry, and the professions to meet and discuss important issues affecting the clinical laboratory testing community.

A keynote address by a news media representative will open the meeting, with discussion on various media topics currently affecting clinical laboratory testing. This will be followed by a plenary session offering public relations, regulatory, and consumer points of view on the use and abuse of clinical laboratory news. The first two concurrent symposia will focus on domestic issues regarding requirements for technological progress and near-patient testing. The second set of symposia will tackle international cooperation on requirements for technological progress and noninvasive and minimally invasive testing. Slated to close the meeting is a discussion on the future, specifically healthcare reform and how it will affect clinical laboratory testing, both operationally and economically. All sessions will be conducted in a roundtable format for ease of discussion, and an expanded poster session will be held.

The annual meeting education program will begin on Friday afternoon, March 25, and continue all day Saturday, March 26. The program will cover timely topics in clinical laboratory testing related to NCCLS standards and guidelines.

NCCLS is an interdisciplinary, nonprofit organization that promotes the development and use of voluntary consensus standards within the clinical laboratory community. NCCLS membership comprises medical library professional associations, agencies of the federal and state governments, manufacturers of laboratory equipment and products, and individual laboratories and health care institutions. For more information, contact Donald W. Thompson, NCCLS, 771 E Lancaster Ave, Villanova, PA 19085; tel (215) 525-2435; fax (215) 527-8399.

Low Birthweight and Infant Mortality in Puerto Rico

ABSTRACT

Objectives. The purpose of this study was to quantify the relative contributions of maternal age, education, marital status, hospital of birth, and use of prenatal care to the high incidence of low birthweight and infant mortality in Puerto Rico.

Methods. An analysis was conducted of 257 537 live births that occurred from 1986 through 1989 among Puerto Rico residents and the 3373 corresponding infant deaths. Binomial multiple regression models were used to calculate the adjusted population attributable risks for each variable.

Results. Our estimates indicate that approximately 6 of every 10 infant deaths on the island are potentially preventable if low birthweight were eradicated, regardless of other associated factors. Eliminating risks associated with sociodemographic and socioeconomic factors (including hospital of birth) would potentially decrease the incidence of low birthweight in Puerto Rico by one third. Specifically, the elimination of risks associated with the socioeconomic disadvantage of women delivering in public hospitals alone would potentially decrease Puerto Rico's low birthweight incidence by 28%, regardless of other factors considered in our study.

Conclusions. Efforts to prevent low birthweight and infant mortality in Puerto Rico should focus on reducing the gap between the private and public sectors. (*Am J Public Health.* 1993;83:1572–1576)

José E. Becerra, MD, MPH, Hani K. Atrash, MD, MPH, Nilsa Pérez, MS, and José A. Saliceti, PhD

Introduction

Puerto Ricans in both the continental United States and Puerto Rico have the highest incidence of low birthweight and infant mortality of all Hispanic groups in the United States.[1] In 1990, the low-birthweight rate in Puerto Rico was 9.1%, compared with 7.0% for the United States as a whole.[2,3] In the same year, the infant mortality rate in Puerto Rico was 13.4 per 1000 live births, compared with the overall US rate of 9.1.[2,4]

In previous studies, investigators have implicated increased birthweight-specific neonatal mortality risks,[1,5] smoking,[6] and inadequate prenatal care[7] as contributors to adverse pregnancy outcomes in Puerto Rico; however, no previous study has quantified the relative contributions of sociodemographic and socioeconomic factors to the high incidence of low birthweight and infant mortality on the island.

This study had two objectives: to assess the relative contributions of maternal age, marital status, maternal education, hospital of birth, and use of prenatal care to the incidence of low birthweight in Puerto Rico, and to assess the relative independent contributions of those same factors to the incidence of infant mortality after accounting for the effect of birthweight. The ultimate goal of the study was to provide public health policymakers in Puerto Rico with accurate information that can guide the design and implementation of prevention strategies to reduce the high incidence of low birthweight and infant mortality.

Methods

From 1986 through 1989, 258 354 live births occurred among Puerto Rico residents.[2] Infant death certificates from 1986 through 1990 were matched to their corresponding birth certificates. Fewer than 2% of these certificates remained unmatched, thus, valid data for the variables under study were available for 257 537 live births and the 3373 corresponding infant deaths.

We defined infant death as the death of a newborn before the end of the first year of life; infant birthweight as low birthweight (< 2500 g) or normal birthweight (≥ 2500 g); maternal age as less than 20 years or 20 years or more; marital status as unmarried (including consensual unions) or married; maternal education as less than 12 or 12 or more years of formal education; hospital of birth as public or private; and prenatal care as none or some prenatal care documented in the birth certificate.

We used the generalized linear model technique to fit a binomial multiple regression model to the data.[8] After considering all possible combinations of main effects of the variables under study, we selected and compared four hierarchical models. Two of these models (models 1a and 1b) included the combined effect of all exposure variables on birthweight. Model 1a included only the main effects, and model

1b added all statistically significant ($P < .05$) second-order interactions. The log-likelihood ratios[9] were 51.6 ($df = 26$, $P < .01$) for model 1a and 32.9 ($df = 23$, $P = .08$) for model 1b. The other two models (models 2a and 2b) added birthweight to the exposure variables and considered infant death as the outcome. Model 2a included only the main effects, and model 2b added all statistically significant ($P < .05$) second-order interactions. The log-likelihood ratios were 105.8 ($df = 57$, $P < .01$) for model 2a and 57.6 ($df = 52$, $P = .27$) for model 2b.

Finally, we estimated the population attributable risk for each variable after adjusting for all other variables included in model 1b and model 2b.[10] The population attributable risk is the proportion of a health outcome potentially prevented if the risk associated with a given factor is eradicated from the population after the data have been adjusted for all other risk factors. For instance, to estimate the population attributable risk of low birthweight for unmarried mothers—adjusting for the simultaneous effects of age, education, hospital of birth, and prenatal care (model 1b)—we calculated the *individual* risks according to the binomial regression model and assumed that each mother was married. We totaled these individual risks to calculate the *expected number* of low-birthweight infants if all mothers had been married and compared that expected number with the actual number of low-birthweight infants observed in the population. The following formula was used:

$$\text{Population Attributable Risk} = 100 \times (\text{Observed} - \text{Expected})/\text{Observed}.$$

Because the models selected showed a good fit to the data, the observed number of low-birthweight infants in the population was very close to the one predicted by the binomial regression model.

Results

According to our study, the average infant mortality rate in Puerto Rico from 1986 through 1989 was 13.1 infant deaths per 1000 live births (76% died in the neonatal period), and the average low-birthweight rate was 8.9 per 100 live births (90% of low-birthweight infants weighed between 1500 and 2499 g at birth). During this period, approximately 1 in 6 mothers were under 20 years of age, 1 in 3 were unmarried, 1 in 3 had less than 12 years of formal education, 2 in 3 gave birth in public hospitals, and 1 in 50 were unable to obtain any prenatal care (Table 1). Of all deliveries in the public sector, 99% occurred in hospitals owned by the Puerto Rico Department of Health. Public sector hospitals were more likely than private sector hospitals to receive mothers under 20 years of age (25% vs 4%), unmarried mothers (45% vs 12%), and mothers with less than 12 years of formal education (50% vs 9%).

TABLE 1—Low Birthweight (< 2500 g) and Infant Mortality Rates, by Selected Maternal Characteristics: Puerto Rico Birth Cohorts, 1986/87 through 1989/90

Maternal Characteristics	No. (%[a])	Low Birthweight[b]	Infant Mortality[b]	Neonatal Mortality[b]
Age y				
< 20	45 010 (17.5)	11.0	16.3	12.6
≥ 20	212 527 (82.5)	8.5	12.4	9.4
Marital status				
Unmarried	84 722 (32.9)	11.1	17.4	12.9
Married	172 815 (67.1)	7.8	11.0	8.5
Level of education, y				
< 12	91 214 (35.4)	10.7	16.1	11.7
≥ 12	166 323 (64.6)	7.9	11.4	9.0
Type of hospital				
Public	165 073 (64.1)	10.5	16.5	12.5
Private	92 464 (35.9)	6.1	7.3	5.5
Prenatal care				
None	5 207 (2.0)	19.9	49.5	39.4
Some	252 330 (98.0)	8.7	12.3	9.4
Total	257 537 (100.0)	8.9	13.1	10.0

[a]Percentage of total.
[b]Rate per 1000 live births.

Low-birthweight rates differed markedly according to the maternal characteristics examined in this study (Table 2). Mothers with no prenatal care were 2.29 (95% confidence interval [CI] = 2.16, 2.42) times more likely to deliver a low-birthweight newborn than were mothers who had some prenatal care. Mothers in public hospitals were 1.73 (95% CI = 1.68, 1.78) times more likely to deliver a low-birthweight newborn than were mothers in private hospitals. Unmarried mothers were 1.42 (95% CI = 1.39, 1.46) times more likely to deliver a low-birthweight infant than were married mothers (infants of single mothers and of mothers living in consensual unions had similar low-birthweight risks). Less educated mothers were 1.35 (95% CI = 1.32, 1.38) times more likely to deliver a low-birthweight infant than were more educated mothers. Mothers 19 years of age or younger were 1.29 (95% CI = 1.25, 1.33) times more likely to deliver a low-birthweight infant than were older mothers.

After adjusting for all other variables included in the model, we found that (1) the low-birthweight risk among mothers with no prenatal care was still 1.99 (95% CI = 1.88, 2.10) times higher than among women who received some prenatal care, (2) the risk among mothers delivering in public hospitals was still 1.55 (95% CI = 1.50, 1.60) times higher than the risk among mothers delivering in private hospitals, (3) the risk among unmarried mothers decreased and was 1.18 (95% CI = 1.15, 1.21) times higher than the risk among married mothers, (4) the risk among mothers 19 years old or younger decreased and was 1.07 (95% CI = 1.04, 1.11) times higher than the risk among older mothers, and (5) the risk among less educated mothers decreased and was 1.05 (95% CI = 1.02, 1.08) times higher than the risk among more educated mothers.

Infant mortality rates also differed markedly according to the maternal and infant characteristics examined (Table 3). Low-birthweight infants were 19.60 (95% CI = 18.28, 21.02) times more likely to die within their first year of life than were normal-birthweight infants. Infants of mothers who did not have prenatal care were 4.03 (95% CI = 3.57, 4.54) times more likely to die within their first year of life than were infants of mothers who did have some prenatal care. Infants delivered in public hospitals were 2.35 (95% CI = 2.16, 2.55) times more likely to die within their first year of life than were infants delivered in private hospitals. Infants of unmarried mothers were 1.58 (95% CI = 1.48, 1.69)

TABLE 2—Relative Risks and Population Attributable Risks of Low Birthweight, by Selected Maternal Characteristics: Puerto Rico Birth Cohorts, 1986/87 through 1989/90

Maternal Characteristics	Crude Relative Risk	Adjusted Risk		
		Model 1a Relative Risk[a]	Model 1b Relative Risk[b]	Population Attributable Risk
Age < 20 y	1.3	1.1	...	1.6
Education < 12 y	...	...	1.1	...
Education ≥ 12 y	...	...	1.0	...
Unmarried	1.4	1.2	...	6.6
Education < 12 y	...	...	1.2	...
Education ≥ 12 y	...	...	1.1	...
Education < 12 y	1.3	1.0	...	3.0
Age < 20 y, unmarried	...	...	1.2	...
Age < 20 y, married	...	...	1.1	...
Age ≥ 20 y, unmarried	...	...	1.1	...
Age ≥ 20 y, married	...	...	1.0	...
Public hospital	1.7	1.5	...	27.6
No prenatal care	...	...	2.0	...
Some prenatal care	...	...	1.6	...
No prenatal care	2.3	2.0	...	2.2
Public hospital	...	...	2.0	...
Private hospital	...	...	1.6	...

Note. The reference group in the relative risk estimates is the group with opposite attributes (i.e., the reference group for unmarried mothers is the group of all married mothers). The population attributable risk is the proportion of low-birthweight newborns potentially prevented if the risk associated with a given factor is eradicated from the population after adjustment is made for all other risk factors.

[a]Adjusted estimates with all main effects in the binomial multiple regression model but with no interactions included.

[b]Stratum-specific estimates with all main effects and statistically significant ($P < .05$) interactions included (hierarchical modeling).

times more likely to die within their first year of life than were infants of married mothers (infants of single mothers and of mothers living in consensual unions had similar risks of death). Infants of mothers with less than 12 years of schooling were 1.41 (95% CI = 1.32, 1.51) times more likely to die within their first year of life than were infants of more educated mothers. Infants of mothers 19 years old or younger were 1.31 (95% CI = 1.21, 1.42) times more likely to die within their first year of life than were infants of older mothers.

After adjusting for all other variables included in the model, we found that (1) the risk of death among low-birthweight infants was still 17.95 (95% CI = 16.72, 19.26) times higher than among normal-birthweight infants, (2) the risk among infants of mothers with no prenatal care was 2.04 (95% CI = 1.82, 2.30) times higher than among infants of mothers with some prenatal care, (3) the risk among infants delivered in public hospitals decreased and was 1.65 (95% CI = 1.50, 1.81) times higher than among infants delivered in private hospitals, (4) the risk among infants of unmarried mothers decreased and was 1.09 (95% CI = 1.01, 1.16) times higher than among infants of married mothers, (5) the risk among infants of less educated mothers decreased and was 0.94 (95% CI = 0.88, 1.02) times that among infants of more educated mothers, and (6) the risk among infants of mothers 19 years old or younger decreased and was 0.99 (95% CI = 0.91, 1.07) times that among infants of older mothers.

The risk of death among low-birthweight infants who had more educated mothers and were born in public hospitals was 1.9 times higher than the risk among low-birthweight infants who also had more educated mothers but were born in private hospitals. On the other hand, we found no difference in the risk of death among normal-birthweight infants who had less educated mothers and were born in public hospitals compared with normal-birthweight infants who also had less educated mothers but were born in private hospitals.

Discussion

Our results confirm that low birthweight is the most important determinant of infant mortality in Puerto Rico. Approximately 6 of every 10 infant deaths on the island could be prevented if low birthweight were eradicated, regardless of other associated factors (Table 3). The eradication of risk associated with the sociodemographic and socioeconomic factors included in our study (including hospital of birth) would potentially decrease the incidence of low birthweight in Puerto Rico by one third (Table 2). The elimination of the risk associated with hospital of birth alone, as a proxy for socioeconomic risk factors, would potentially decrease the incidence of low birthweight in Puerto Rico by 28%, regardless of other factors considered in our study.

By considering the impact of sociodemographic and socioeconomic factors on the entire population, we have demonstrated that the independent contribution of most of these factors was generally small after accounting for hospital of birth. Specifically, the independent contributions of age and marital status to the incidence of low birthweight were substantially lessened after accounting for hospital of birth. Therefore, health planners should reconsider the widely held expectation that infant mortality in Puerto Rico will significantly improve if interventions focus on younger pregnant mothers.

Although we could postulate an etiologic role for hospital of birth in contributing to the incidence of infant mortality,[1,5] it is not plausible to consider hospital of birth as a causal factor in the incidence of low birthweight. More likely, hospital of birth is another marker for socioeconomic disadvantage unaccounted for by variables such as maternal education and marital status. It is reasonable to assume that most patients served by the public sector in Puerto Rico lack private health insurance.

Hospital of birth may reflect nutritional practices, personal habits (such as illicit drug use, alcohol use, and smoking practices[6]), access to prenatal care,[7] psychological and social stresses,[11] and parenting skills, among other behavioral, social, environmental, and economic disadvantages that have been traditionally associated with the public health concept of race.[12]

The usefulness of the concept of race in medical and public health research has been reviewed recently.[12–17] Although the Puerto Rico Department of Health collects data on race in its vital statistics system, race has never been used in the analyses and reports of these data because it is believed to contain unavoidable and significant misclassification. In Puerto Rico, there is as yet no risk marker equivalent to

the public health concept of race to help identify populations at high risk of low birthweight and infant mortality and thus rally support and target intervention strategies to prevent these outcomes. We propose that hospital of birth, instead of the public health concept of race, be used in Puerto Rico to define health care and pregnancy outcome gaps between the public and private sectors.

Our study also demonstrates, however, that hospital of birth is a significant independent contributor to infant mortality after controlling for birthweight, regardless of other sociodemographic factors. This finding suggests that the survival of infants delivered in public hospitals could be improved regardless of the sociodemographic profile of the mother.[1,5]

We found a complex but interesting relationship between maternal education and hospital of birth. The association between hospital of birth and infant mortality was substantially reduced among infants of less educated mothers. The relative risk of death associated with public hospitals was 60% to 90% higher among infants of more educated mothers but only 0% to 20% higher among infants of less educated mothers. This interaction is also reflected in the complex relationship between birthweight, hospital of birth, and maternal education (Table 3). The association between maternal education and infant mortality seems more pronounced among infants delivered in private hospitals. Conversely, it could be argued that the association between hospital of birth and infant mortality is more distinct among the more educated mothers. In fact, the (absolute) risk of death among low-birthweight infants who had less educated mothers was 86.5 per 1000 live births in public hospitals compared with 70.7 in private hospitals. Among low-birthweight infants who had more educated mothers, the risk of death was 111.3 per 1000 live births in public hospitals compared with 59.1 in private hospitals (data not shown). Therefore, maternal education may not fully reflect socioeconomic status among low-birthweight infants. On the other hand, the risk of death among normal-birthweight infants who had less educated mothers was 5.7 per 1000 live births in public hospitals compared with 5.6 in private hospitals. Among normal-birthweight infants who had more educated mothers, the risk of death was 5.1 per 1000 live births in public hospitals compared with 3.3 in private hospitals (data not shown). Therefore, normal-birthweight infants who had less educated mothers were at higher risk of death regardless of where they were born.

TABLE 3—Relative Risks and Population Attributable Risks of Infant Mortality, by Selected Maternal Characteristics: Puerto Rico Birth Cohorts, 1986/87 through 1989/90

Maternal/Infant Characteristics	Crude Relative Risk	Adjusted Risk

Note. The reference group in the relative risk estimates is the group with opposite attributes (i.e., the reference group for low-birthweight infants is the group of all normal-birthweight infants). The population attributable risk is the proportion of infant deaths potentially prevented if the risk associated with a given factor is eradicated from the population after adjustment is made for all other risk factors.

[a]Adjusted estimates with all main effects in the binomial multiple regression model but with no interactions included.

[b]Stratum-specific estimates with all main effects and statistically significant ($P < .05$) interactions included (hierarchical modeling).

We did not attempt to assess the full effect of prenatal care on low birthweight and infant mortality. In fact, our classification of prenatal care as "none" or "some" reflects how crudely we were able to approach this matter. Using vital records in Puerto Rico, other researchers have found no appreciable differences in pregnancy outcomes examined according to the trimester in which prenatal care began.[7] Therefore, the low population attributable risks associated with prenatal care should not be viewed as evidence of ineffectiveness but as evidence of our inability to measure what really works and what does not work in prenatal care. Nevertheless, our analysis suggests that a lack of prenatal care either sorts out those at high risk of low birthweight and infant mortality or is associated with a twofold increase in both, regardless of other risk factors. The impact of this increased risk on the population as a whole is constrained by the low prevalence of women with no prenatal care on the island.

The results of this and previous stud-

ies[1,5] are being used to document the need to improve the perinatal health care provided in Puerto Rico's public hospitals, and a special tax has been enacted for making such improvements. Few neonatal intensive care beds are available in Puerto Rico's private sector, because most high risk neonates are usually transferred to tertiary, public health care facilities. Therefore, the special tax revenues will be used to reduce infant mortality by improving the survival of newborns in Puerto Rico.

The Puerto Rico Department of Health has also launched a major initiative to improve the access, quantity, and quality of prenatal care in the public sector. Health officials in Puerto Rico agree that the most cost-effective way to reduce infant mortality is to prevent low birthweight through universal access to timely and good prenatal care.[18] Of course, further studies are needed to sort out the risk factors associated with low birthweight due to preterm delivery and to intrauterine growth retardation because vital statistics data do not provide reliable information on gestational age.[19] Further studies are also needed to assess how life-styles and personal habits, such as illegal drug use, smoking, and alcohol use, relate to pregnancy outcomes in Puerto Rico.

The prevention of low birthweight and infant mortality, as with most health outcomes, is seldom related to specific technological interventions. Public health officials and clinical practitioners can significantly improve infant mortality in Puerto Rico, however, by lowering birthweight-specific infant mortality risks.[1] Long-term prevention strategies designed to improve infant mortality, on the other hand, more likely will be associated with reducing the gap in low birthweight between the private and public sectors. □

Acknowledgments

This study is the result of a collaborative agreement among the Centers for Disease Control and Prevention, the Health Resources and Services Administration, and the Puerto Rico Department of Health, which assigned a perinatal epidemiologist to the Commonwealth of Puerto Rico.

Prescription and Nonprescription Drug Use among Black and White Community-Residing Elderly

ABSTRACT

Objectives. To examine and compare concomitants of prescription and nonprescription drug use of Black and White community-dwelling elderly.

Methods. Information on prescription and nonprescription drug use, demographic and health characteristics, and use of health services was obtained from a probability-based sample of Black (n = 2152) and White (n = 1821) community-resident elderly in the Piedmont area of North Carolina. Descriptive statistics were calculated. Linear regression, in which sample weights and design effects were taken into account, was used for the final models.

Results. For prescription drug use, 37% and 32% of the variance was explained for Whites and Blacks, respectively (6% and 5% for nonprescription drugs). Health status and use of medical services were the strongest predictors of prescription drug use for both races (with Medigap insurance also important for Whites and Medicaid important for Blacks). Demographic characteristics and self-assessed health were significant factors in the use of nonprescription drugs. Race independently predicted use of both types of drugs but explained only a small proportion of the variance.

Conclusions. Health status and use of health services are importantly related to prescription drug use. Nonprescription drug use is difficult to explain. (*Am J Public Health.* 1993;83: 1577–1582)

Introduction

The elderly, who represent 12% of the population, have been reported to take 30% of all prescription medications.[1] Higher prescription drug use has been reported for persons who are older, female, and in poorer health; who have more impaired activities of daily living; and who have a secondary reimbursement source (e.g., health insurance or Medicaid). Those who have a higher income, who are employed, or who have had more years of education, and those who are Black have been found to be less likely to use prescribed medications.[1–11] The finding of lower medication drug use among Blacks[11] is particularly perplexing because, by most criteria, their health is poorer[12]; consequently, their use of medications would be expected to be greater than that of non-Blacks.

Although the elderly are also frequent users of nonprescription drugs,[5] information on the factors associated with the use of such drugs is scantier than that for prescription drugs. In general, reported findings indicate that women and those who are White are more likely to be taking nonprescription drugs, but the association of nonprescription drug use with age is unclear.[4,5,10,11] A number of reasons for nonprescription drug use have been proposed: these drugs may be used by persons who perceive medical care to be unavailable, by those who are more anxious, or as a substitute for or in conjunction with prescription drugs.[2,13–15] Factors consistently reported to be associated with prescription drug use (e.g., income, education, socioeconomic level, health status) are not consistently related to use of nonprescription drugs.[16]

Few studies have examined racial differences in drug use while taking into account interrelated predictors of such use.[13–15,17–22] The main purpose of the present study, then, was to examine determinants of the use of prescription and nonprescription drugs by elderly Black and White community residents using a multivariate approach. Second, we wished to determine whether the model that explains prescription drug use would also explain nonprescription drug use.

Methods

Sample

The data come from the in-home baseline survey (1986 to 1987) of the Duke Established Populations for Epidemiologic Studies of the Elderly.[23,24] In brief, the study sample consists of a stratified

probability household sample of 4163 community residents aged 65 or older living in five adjacent urban and rural counties in the Piedmont area of North Carolina. To increase statistical precision, Blacks were oversampled, constituting 54% of those interviewed compared with 35% of the same age population. Analysis weights take initial nonresponse into account, correct for the oversampling of Blacks, and allow inference to the five-county area at the time of the survey. The Duke study was approved by the Duke University Medical Center Institutional Review Board, and informed consent was obtained from each participant before data were gathered.

The present analysis excluded 30 subjects who were neither Black nor White, and 160 subjects with only proxy data since information on their self-assessed health status was unavailable. Hence, the analysis data set included 2152 Black and 1821 White elderly, of whom 1727 (80.3%) and 1588 (87.2%), respectively, responded to each item analyzed.

Data Collection

Information was obtained by means of a 90-minute, in-person interview in the home. The interview schedule has been published.[23] Relevant available data include (1) demographic characteristics; (2) limited information on health conditions (i.e., the presence of a heart condition, stroke, cancer, diabetes, hypertension), self-assessed health (a single item), and physical health functioning; and (3) measures of use of selected health care services and professionals, income, and health insurance.

The name, strength, and dosage form of each medication taken in the prior 2 weeks or to be taken as needed were recorded.[11]

Drug Data Entry

Each drug was assigned a unique four-digit generic code from the DPICS and IN-DPICS coding system[5] using a locally developed interactive data entry program,[11] and each was further numerically coded to indicate whether it was a prescription or nonprescription product. Reliability of drug data entry, which was tested by re-entering a 5% sample, was found to be highly satisfactory, with the rate of coding errors estimated to be 1.63% (95% confidence interval = 0.71%, 2.55%).

Model Development

A health care services use model[25] was chosen to explore prescription and nonprescription drug use. Specifically, use of medications was expected to be influenced by demographic characteristics, health status, and factors that facilitate or hinder drug use.

The demographic characteristics included race (Black/White), sex, age and education (both in years), marital status (married/not currently married), and current residence in an urban or rural area.

Health status was assessed by three measures. The first, a medical status score, summarized the medical impact of five common chronic health conditions (heart condition, stroke, cancer, diabetes, and hypertension). These physical health conditions were the only ones present that had any medication-related relevance. The medical status score reflected the averaged evaluations (summed over all five conditions) made by 36 clinicians experienced in the care of the elderly; the evaluations were made regarding the extent to which each condition had an impact on health status. In making these evaluations, the clinicians considered all available information. For instance, in rating heart condition, they took into account any report of heart attack and, if there were any such reports, factored in how many, how recently, and whether there was a related hospitalization. The manner of development of the medical status scale ensured that it had content validity; it also had construct validity, summary scores being related to selected aspects of health services use, self-rated health, and activities of daily living in the expected manner. Thus, this measure is valid and maximizes the information available.

The two additional measures of health status included self-rated health (a 4-point scale in which 0 = poor and 3 = excellent) and a measure of functional physical health (three items of the Rosow and Breslau scale,[26] in which the score was the number of items the subject had difficulty performing, with missing values imputed where possible).

Items facilitating or hindering drug use included the number of outpatient visits in the past 12 months to a medical professional for a physical health problem, whether the same health care professional was usually seen on each visit, and hospitalization in the previous year. Additionally, they included not being on Medicaid (which in North Carolina pays for prescription medications); enrollment in Medicare (which financially facilitates access to medical care and hence to receipt of a prescription); supplementary health insurance (which may pay toward prescription medications); and adequacy of income.

Statistical Analysis

Descriptive statistics were calculated separately for Blacks and Whites. To examine the impact of missing data, use of prescription and nonprescription drugs by full and partial responders was compared using Student's t test. For all other variables (demographic, health status, facilitating/hindering characteristics), information on the individual comparisons was combined and an omnibus test was carried out (Fisher's Inverse Chi-Square Method based on P values derived from Wilcoxon's signed rank test or the Kruskal-Wallis statistic).[27]

For prescription and nonprescription drugs, the proportions of Black and White respondents using at least one drug were compared using chi-square tests. Comparison of mean drug use by race was made using Student's t test.

Multivariate models were constructed using forward linear regression, introducing blocks of demographic, health status, and facilitating/hindering variables successively as predictors of the number of drugs used. Separately for prescription and nonprescription drug use, models were run for Blacks, Whites, and both races combined; the latter model included an indicator variable for race. All models used analysis weights. Initial models were run in SAS, using procedure REG[28]; final models considered sample design effects and were implemented in SURREGR.[29,30]

To determine the impact of excluding partial responders from the models, all but the final stage of each series of models was run with partial responders included where they were not automatically deleted by the software.

Results

Sample Characteristics

Table 1 shows the characteristics of responders in the current sample. For both Blacks and Whites, those who responded to each item were less impaired than those who did not ($P < .0001$). On average, partial responders reported more prescription and fewer nonprescription drugs than full responders. They tended to be older, less educated, in poorer functional and self-assessed health, and more likely to have been hospitalized in the previous year. If Black, they were less likely to be married; if White, they were more likely to be female and less likely to have

supplementary health insurance. The exclusion of partial responders from analysis appears to have had little impact on the findings.

Prevalence and Extent of Drug Use, Both Types

In the present study, 76% of White and 74% of elderly Black community residents took at least one prescription drug, a nonsignificant difference. However, Black users took significantly fewer prescription drugs (mean = 2.79, SD = 1.75) than did White users (mean = 3.19, SD = 2.20; $t = 5.53$, $df = 2693$; $P < .0001$). Only 67% of Blacks compared with 76% of Whites ($\chi^2 = 43.26$, $df = 1$; $P < .0001$) reported taking nonprescription drugs. Of those reporting such use, Blacks again took significantly fewer nonprescription drugs (mean = 1.69, SD = 1.01) than did Whites (mean = 1.89, SD = 1.18; $t = 4.86$, $df = 2804$; $P < .0001$).

Although here the health status of Blacks appears to be similar to that of Whites, Blacks use fewer drugs of either type. They are also less likely than their White counterparts to be married and to have supplementary health insurance; they also have less education and are in more straitened economic circumstances.

Predictors of Prescription Drug Use

For elderly White community residents (Table 2), demographic characteristics explained a minimum amount of variance (0.8%), those with poor education being heavier consumers of prescription drugs. When health status was also considered, an additional 30% of variance in prescription drug use was explained. For each health measure, poorer standing indicated greater prescription drug use. A further 6.4% of variance was explained by facilitating/hindering characteristics, for a total of 37.2% of variance explained. Of the latter characteristics, the number of visits to a physician, the same physician seen on each occasion, overnight hospitalization in the previous year, and the presence of Medicaid and of supplementary health insurance were significant predictors of prescription drug use. With the inclusion of the facilitating characteristics, level of education lost its significance but area of residence became important: among White elderly, urban area residents were likely to be taking more prescription drugs than rural area residents.

For elderly Black community residents (Table 3), demographic characteristics explained 3.2% of the variance in pre-

scription drug use, with only sex being statistically significant: Black women were higher users of prescription drugs (or rather, Black men were particularly low users). When health status was also considered, 22.9% of the variance was explained. Poor health status as assessed by each of the three measures predicted increased prescription drug use. Addition of the facilitating/hindering variables increased the amount of variance explained to 31.5%, with making more frequent visits to a physician, consistently seeing the same physician, having Medicaid, and having Medicare being significant predictors of prescription drug use.

Finally, a model was run that included both Black and White elderly residents (tables available from the authors). This model explained 36.6% of the variance in prescription drug use. Race per se was statistically significant and contributed 1.3% to the overall variance. All characteristics found to be significant predictors of prescription drug use in the separate models for White elderly and Black elderly (with the exception of Medicare, significant for Black elderly, and Medigap insurance, significant for White elderly) were statistically significant. Race interaction effects showed that Black elderly with impairments on the Rosow-Breslau[26] and Black elderly women who had been hospitalized in the previous year were likely to use fewer drugs than their White counterparts, whereas White elderly women who reported their health to be poorer were particularly high prescription drug users.

Predictors of Nonprescription Drug Use

Among elderly White community residents (Table 4), all variables combined explained 6.0% of the variance (demographic characteristics explained 2.8%, and the addition of health status explained 5.4%). Female sex, urban residence, younger age, more education, poor self-rated health and medical status, and an increased number of physician visits were statistically significant predictors.

The explanatory power of the model was less for elderly Black community residents (Table 5). In all, 4.8% of the variance in nonprescription drug use was explained. The only important characteristics were being female, considering one's health to be poorer, having supplemental health insurance, and not being on Medicaid.

A model that included information from both Black and White elderly residents explained 6.4% of the variance in

nonprescription drug use. Race per se was statistically significant, contributing 0.7%. All characteristics found to be statistically significant in either the nonprescription model for White elderly or that for Black elderly were also statistically significant in the combined race model, with the exception of Medicaid and supplemental health insurance.

Discussion

These data allow us to compare the characteristics of Black and White elderly who represent all socioeconomic levels and who live in both urban and rural settings in a defined geographic area. As such, our data are unique, permitting comparisons not hitherto feasible. While descriptive information on the prescription and nonprescription drug use of minority groups exists,[8,11] studies of drug use in the elderly based on multivariate techniques have been restricted by the relative youth of sample members (under age 65), small sample sizes, limited representativeness, and lack of information on race.[6,10,14]

We found that, with other factors controlled, race made a statistically significant, if substantively small, contribution to explaining prescription drug use. The multivariate health care services use model explained up to 37% of the variance in prescription drug use. Demographic characteristics had little explanatory power although, in the absence of other data, they seemed to act as proxies for health status and use of health care services. Similarly, the importance of other characteristics (e.g., living in an urban area where transportation may be easier and pharmacies more numerous) only became evident with concomitant consideration of additional information.

It has been suggested that access to prescription drugs is based on formal health system factors.[13,14] Certainly here, prescription drug use is predominantly explained by health status and use of the health care system, just those factors that can result in a prescription.[31] It is also important to note that having Medicaid (which pays for drugs for the medically indigent) was a significant predictor of prescription drug use.

Although the primary determinants of prescription drug use (i.e., poor health status, more frequent medical visits, and the same physician seen on those visits) are similar for elderly Black and White community residents, there are some unique differences. For example, living in an urban area and recent overnight hospitalization are important in explaining prescription drug use for elderly Whites but not for elderly Blacks.

In common with other investigators,[13–15] we also find that the health services use model explains nonprescription drug use poorly. Access to nonprescription drugs is not bound by medical or legislative constraints. Unlike the case for prescription drug use, demographic characteristics were particularly important: being White, female, younger, better educated, and an urban area resident were predictive of nonprescription use. Indeed, these are the people to whom nonprescription drug use is targeted. While poorer health might also be relevant, it is unclear from these data whether nonprescription drugs substituted for or supplemented the use of prescription drugs.

The nonprescription use models for Black elderly differ from those for White elderly in that they reflect concern about health, particularly by women, and about the availability of some money to spend on it.

In the present study, race per se is a significant predictor of both kinds of drug use. Black elderly, particularly Black men, are likely to take fewer prescription drugs. However, the reasons for this are unclear. Possibly physicians prescribe differently for Black elderly as compared with White elderly.[10] Another possibility is that Black elderly may face restrictions in economic access to drugs. A larger proportion of White elderly than of Black elderly have supplementary health insurance, which may pay for prescription drugs. Conversely, a higher proportion of Black elderly are on Medicaid, and while Medicaid facilitates the use of prescription drugs, not all physicians will accept Medicaid patients and the program places restrictions on the number of reimbursable drugs that can be received in a given time interval. Other financial restrictions may also be present. Thus, the presence of Medicaid modifies but does not close the racial gap in prescription drug use. With respect to nonprescription drug use, Black elderly, in particular Black men, are again low users, but elderly Black users of nonprescription drugs appear to have a financial background comparable to that of White elderly.

The present study has some limitations. For one thing, current analysis is based on cross-sectional data. We are assuming that poor health leads to the use of medical care services, which results in prescriptions and the use of prescription drugs. The reverse is possible but is dis-

tinctly less likely. For another thing, information from some sample members is incomplete; however, this appears to have had little effect on the findings, except perhaps to make them slightly more conservative. More important, the lack of information on psychiatric conditions and on other physical conditions such as arthritis may have decreased the explanatory power of the models, particularly regarding nonprescription drugs. Lastly, current analyses also do not address the issue of appropriateness of drug use. That will be the focus of a future study.

Despite these limitations, the current study provides population-based information for both Black and White elderly residents, showing that the use of prescription drugs is largely governed by the same characteristics for each group (although unique race characteristics still exist). In addition, the study points to the importance of the Medicaid program in equalizing access to prescription drugs, and it shows that an alternative model is needed to explain the use of nonprescription drugs. □

Insurance, Income, and Access to Ambulatory Care in King County, Washington

Barry G. Saver, MD, MPH, and Nancy Peterfreund, MHA

ABSTRACT

Objectives. We studied simultaneous effects of income and insurance on access measures in an indigent population, focusing on Medicaid and the marginal effects of increasing income.

Methods. Surveys were distributed in waiting rooms of county clinics and welfare offices. Models examined insurance (private, Medicaid, or none), income (to twice the poverty level), single-parent status, age, gender, and presence of a regular source of care; first-order interactions were evaluated.

Results. In terms of ease of access, postponing care, and having a regular source of care, uninsured respondents fared worst and Medicaid recipients were at an intermediate level. However, relative to those with private insurance, Medicaid recipients had four times the odds, and uninsured respondents twice the odds of being denied care. Income had no consistent effect; however, older, poorer people may have greater problems. For preventive services, income was significant, while differences between Medicaid and private insurance were generally not significant.

Conclusions. Except for denial of care, access for indigent people is improved by Medicaid but remains worse than the access of those with private insurance. Income had variable effects, but support for income criteria used for public insurance eligibility was not found. (*Am J Public Health.* 1993;83:1583–1588)

Introduction

Access to medical care for indigent populations remains a problem in the United States. Income and insurance are two factors widely regarded as being important for access. However, little evidence exists indicating whether income in the range used in determining Medicaid eligibility has a meaningful impact on access. Enacted to provide health insurance coverage to the indigent, Medicaid currently covers less than 50% of those below the federal poverty level, a proportion that has been declining since 1975.[1] Furthermore, states set benefits and eligibility levels; thus, in 1988, the maximum family income for Medicaid eligibility through Aid to Families with Dependent Children ranged from 14.6% of the federal poverty level in Alabama to 85.8% in Utah.[2]

Medical insurance, especially Medicaid, does not guarantee adequate access. Medicaid has been reported to eliminate the lower rate of physician visits experienced by indigent populations; however, there is debate as to whether this holds after adjustment for health status.[3–10] A study of Medicaid expansion for obstetrical care in Tennessee did not indicate improvements in obtaining timely prenatal care or in birth outcome,[11] although termination of Medicaid benefits has been shown to result in worse access and outcomes.[12] Medicaid recipients and uninsured persons have been found to have increased rates of avoidable hospitalization.[13,14]

Income has been reported to be an important determinant of access,[4,5,14–21] but many studies have not controlled for its association with insurance status. People at upper income levels, whether insured or not, probably experience fewer barriers to care than do people at lower levels, and their inclusion in comparisons may produce effects not present in lower income groups. One study of insured adults found that income was correlated with access, but the study included too few poor persons to analyze whether this effect was attributable to income or Medicaid.[16] In women 45 to 64 years of age, lack of insurance coverage was the strongest predictor of receiving preventive services, while income was generally not a significant predictor.[22] In a clinic population, a study limited to persons with incomes up to twice the federal poverty level found insurance to be highly significant and income not significant for having a regular source of care and having at least one physician visit in the previous year.[23] In a national survey, Medicaid was a fairly important factor for predicting better access for children under 5 years of age, while income had a modest and not always significant effect.[24]

Having a regular source of care can be considered both a predictor and a measure of access.[5,8,16,18,25] Being able to identify a specific care provider has been reported to be a crucial factor in improved access.[6,14,15] In a recent study, income was not significant in predicting having a regular source of care; however, poor individuals were much more likely to lack a regular source of care for financial reasons. Those who were insured were twice as likely as those who were uninsured to have a regular source of care.[26]

This paper was accepted March 23, 1993.

Inadequate access may also result in deferral and denial of care. Six percent of the US population has been estimated to have needed but not received care[18,19]; estimates vary (e.g., 0.4%,[27] 1.5% [3.2% for low-income persons],[28] and 2%[15]) as to the percentage of people who have been denied care as a result of lacking money or insurance. Those with public insurance have reported the same[19] or a higher[15] frequency of being denied care as have those who are uninsured.

Between 1980 and 1990, the population of King County, Washington, increased approximately 25%, with greater growth occurring outside of Seattle and in the low income population. According to the 1990 census, the incomes of 15.6% of the county population are below 200% of the federal poverty level, and the incomes of 4.2% are below the federal poverty level. These are probably conservative estimates given the groups that tend to be underrepresented in the census. Approximately 3.4% of county residents and 2.2% of those residing outside of Seattle are Medicaid recipients. Approximately two thirds of the county's population lives outside of Seattle.

As the population increased, concern developed that access problems were increasing among poor residents, especially in areas outside of Seattle, and that county facilities were becoming overburdened. As part of a process for creating a master plan for county health services, the Seattle–King County Department of Public Health decided to survey access problems of current and potential users of its health care services.

We hypothesized that, in this relatively indigent population, insurance status would strongly predict access and income would not predict access; also, we hypothesized that Medicaid recipients would be at a level of access intermediate between privately insured and uninsured persons. Furthermore, we believed that single parenthood, in addition to its association with Medicaid eligibility, might serve as an indicator of greater socioeconomic difficulties.

Methods

Data Source

The survey instrument was developed by the health department and pilot tested with a focus group of 15 people chosen to be similar to the population expected to be present in the survey locations. Surveys were available in English, Spanish, Vietnamese, and Cambodian. They were collected anonymously in the waiting rooms of county clinics and welfare offices during spring through fall 1989 (south and east King County) and in fall 1990 (southwest King County). All persons present were asked to participate, and the surveyor was available to provide any needed assistance. Refusal rates were 5% to 10% on any given day.

Respondents were asked to estimate their monthly household income. Insurance status was ascertained by asking for all methods of paying medical bills; possible responses were self-pay, medical coupons (Medicaid), private insurance, unable to pay, and other.

Respondents were asked to rate, on a five-point Likert scale (ranging from "very easy" to "very hard"), how difficult it was for them to obtain checkups, illness care, mental health counseling, dental care, and affordable prescription drugs. Also, they were asked where they usually sought health care; choices included no regular source of care, health department clinics, community clinics, private doctors or clinics, emergency rooms, and other. Finally, they were asked whether, in the last 2 years, they (1) had put off seeking care because of lack of money or insurance, (2) had been denied care, and (3) had received the following preventive services: checkups, blood pressure checks, breast exams, and pelvic exams or Papanicolaou smears.

Analysis

Insurance status was classified as uninsured, Medicaid, privately insured, and both Medicaid and private insurance. The number of persons in the last category was too small to produce reliable estimates; thus, results for this group are not presented. Persons with only "other" coverage (e.g., Veterans Administration care) were also excluded.

Income was converted to a percentage of the federal poverty level for the year of the survey; categories were poor (<100% of the federal poverty level), near poor (100% through 149% of the federal poverty level), and other low income (150% to 200% of the federal poverty level). Expression of income as a continuous fraction of the federal poverty level did not significantly alter results of any of the analyses.

Respondents who reported not having a place they usually went to receive care or using a hospital emergency room were considered not to have a regular source of ambulatory care.

The Likert-scaled items were used as dependent variables in linear regressions performed with SPSS 4.0 (SPSS Inc., Chicago, Ill). In univariate analyses of these variables, linearity tests were used for income and age and F tests were used for differences of means for the other variables. Logistic regressions for categorical variables were performed with EGRET (Statistics and Epidemiology Research Corp., Seattle, Wash). Univariate significance for categorical outcomes was assessed with chi-square tests, and trend tests were used for income and age. All first-order interaction terms were evaluated; interactions are reported if they were either significant at $P < .01$ or significant for more than one of the measures at $P < .05$.

Results

Respondent Characteristics

A total of 2508 surveys were available for analysis. To remove Medicare as a possible confounder, persons 65 years of age or older (11) were excluded. Respondents who did not report income (152) or family size (546), did not report insurance status or reported only "other" (28), or indicated a family income greater than 200% of the federal poverty level (147) were not included in subsequent analyses. Respondents who reported incomes greater than 200% of the federal poverty level were excluded because some respondents clearly reported annual instead of monthly income. After these exclusions, 1624 surveys (64.8%) remained for analysis.

Respondents were predominantly female, poor, and Medicaid recipients (see Table 1). The mean age was 30 for women and 34 for men. The mean income was 84% of the federal poverty level for women and 81% for men; the median income was 76% of the federal poverty level. Half had Medicaid and 28% were uninsured. Only 0.5% of respondents lived alone, and children were present in 97.5% of all households. Those excluded by the above criteria were more likely to be male (25%), not to be single parents (71%), and to have either private insurance (35%) or no insurance (38%).

Analysis

The relative contributions of the different predictors were examined with linear regression models for the measures of perceived ease of access (Table 2), and with logistic regression models for the other, dichotomous outcome measures (Tables 3 and 4). Unadjusted data are discussed only when results of the regression

analyses differ notably from unadjusted results or when they convey significant additional information.

For perceived ease of access, average scores indicated check-ups (2.39) and illness care (2.35) were easiest to obtain, prescription drugs (2.84) were somewhat harder to obtain, and mental helath (2.97) and dental care (3.14) were the hardest to obtain, reaching averages of neutral to slightly difficult. Lacking a regular source of care was reported by 16% of those with private insurance, compared with 31% of Medicaid recipients and 48% of the uninsured. Putting off care was common for all respondents, but more common for the uninsured (81%) than others (58%). Receipt of the different preventive services ranged from 60 to 75% of respondents overall.

For all of the perceived ease of access measures and the access barriers (deferring care, being denied care, and having no regular source of care), insurance status was the strongest predictor; for receipt of preventive services, insurance status was significant but was not the most important factor. In general, uninsured respondents had the worst access, and Medicaid recipients were at an intermediate level of access and often significantly different from both of the other groups. For example, being uninsured shifted responses for perceived difficulty approximately one point on the five-point scale; Medicaid status shifted responses one-fourth to one-half point.

A striking exception to this trend is

that Medicaid recipients were most likely to report denial of care (OR = 3.9) while uninsured respondents were at an intermediate level (OR = 2.2) (Table 3). These odds ratios were only slightly decreased by adjustment, and it should be noted that even 10% of privately insured respondents reported denial of care.

Even before adjustment, income was significant only for some of the measures of perceived ease of access and barriers to access. In instances in which it was significant, lower income persons fared worse. After adjustment, some of these trends disappeared, and in the other cases significant interactions were found (Tables 2 and 3). In contrast, income remained strongly associated with receipt of preventive services after adjustment, with the poor and near poor having only about half the odds of the highest income group of receiving these services (Table 4).

Five significant income interactions were found, four of which were age–income interactions Tables 2–4). Their interpretation was not completely consistent but suggests, overall, that older, poorer respondents had poorer access. The fifth interaction, between income and single-parent status, involved receipt of illness care. Single parents had a trend for decreasing perceived difficulty with decreasing income, an effect opposite that observed before adjustment, while others had a smaller trend for increasing difficulty with decreasing income (Table 2).

After adjustment, having a regular source of care remained a strong predictor of improved access on all of the measures. For ease of obtaining checkups, there was a significant interaction between having a regular source of care and single-parent status. Not having a regular source of care increased the difficulty by more than a full category for single parents and by about two thirds of a category for those who were not single parents (Table 2).

Single-parent status was significant only in interactions. In addition to the two interactions discussed above, single-parent status interacted with age for having a regular source of care. Single-parent status had no discernible effect for respondents up to age 40; however, for respondents more than 40 years of age, single parents had four times the odds of those who were not single parents of lacking a regular source of care (Table 3).

Gender had no discernible effect on perceived ease of access after adjustment (Table 2); before adjustment, men reported significantly increased difficulty in obtaining checkups and illness care. Men were twice as likely as women to lack a regular source of care but half as likely to report deferral or denial of care (Table 3). Men were also less likely to have had a checkup, and they showed a trend in this direction for blood pressure checks (Table 4) that had been significant before adjustment.

Increasing age generally correlated with greater perceived difficulty (Table 2) and decreased odds of having received preventive services (Table 4).

Respondents from county clinics and welfare offices reported similar access problems. In instances in which they differed, those from welfare offices were more likely to report denial of care (OR = 1.5) and less likely to have received a breast examination (OR = 0.8). Respondents from welfare offices who had the lowest incomes were more likely than others to report putting off care; those with the highest incomes were less likely to defer care. Respondents from welfare offices who did not have a regular source of care reported slightly more difficult access to checkups and illness care than did those from county clinics (data not shown).

Discussion

In our population, insurance status predicted the greatest differences for perceived ease of access and barriers to access, and even many privately insured respondents reported access difficulties. For receipt of preventive services, insurance was one of several important predictors. Generally, Medicaid was associated with access measures that were at an intermediate level between private insurance and lack of insurance coverage. The finding that Medicaid recipients were even more likely to experience denial of care than were uninsured respondents was unanticipated and troubling. The reasons for this finding are unclear but may be related to recipients being unaware of which providers accept Medicaid and, perhaps, the greater likelihood of uninsured persons to defer care. Given such findings, the suggestion that access problems of poor uninsured persons can or should be addressed by Medicaid expansion appears unrealistic.

Associations involving income were less clear cut than those involving insurance. In general, adjustment for other factors eliminated the effects of income on perceived ease of access and barriers to care, but an income–age interaction was significant for three of the measures. These interactions suggest that older (over 30), poorer people in our population have more difficulty obtaining access to care, consistent with results from a study of preventive services in women that did not control for insurance.[29] Increasing income increased the odds of receiving blood pressure checks, breast exams, and pelvic exams or Papanicolaou smears. It is not clear why, contrary to the results of Woolhandler and Himmelstein,[22] income had

little predictive value for ease of access and access barriers but was a strong and fairly consistent predictor for receipt of preventive services. Conceivably, our findings could have resulted from the frequent exclusion of preventive services from insurance coverage and their perception as "optional" services. These observations need to be clarified in future investigations, but their equivocal nature does not provide support for arbitrary income cutoffs less than twice the poverty level for Medicaid or other publicly supported health insurance.

Reporting a regular source of care was strongly associated with improved access on all measures. Consistent with previous findings, income was not an important predictor, and insurance was the most important predictor, of having a regular source of care.[26] Causality should not be inferred from such associations since, for example, those having a regular source of care may be persons who are more likely to seek care. This could explain why men were less likely to report a regular source of care but also less likely to report postponing and being denied care. Assigning persons without a regular source to providers may or may not improve access for those who have not found a source on their own.

Single-parent status showed no consistent effect. For many people, Medicaid eligibility is dependent on eligibility for Aid to Families with Dependent Children and, hence, single-parent status; however, such a criterion does not appear to be sensible from the perspective of access.

A number of weaknesses of the study should be considered. First, the respondents represent a use cohort, and responses are subject to a volunteer bias. However, representative samples of indigent people are difficult to obtain. Telephone samples underrepresent indigent persons,[18,30] which, although having little effect on population estimates, may seriously bias studies of the poor. Second, the number of persons in the highest income group in this study was relatively small, decreasing the power to detect effects of income. Third, more than 20% of the responses were excluded as a result of missing information concerning family size, and those respondents who were excluded may have been different from other respondents (e.g., mostly persons living alone). Fourth, because of the sampling strategy, men were underrepresented in the sample. Fifth, the questions used to elicit information about receipt of preventive services may have resulted in significant overestimates, since some respondents may have considered an illness-related visit to be a checkup and women receiving a pelvic exam may have mistakenly assumed that a Papanicolaou smear was performed or may have been unaware of the distinction between the two procedures. Finally, a number of the measures depend on actual or perceived need for services, but the survey instrument contained no information to assess health status and perceptions.

However, given that surveys were distributed in county clinics and welfare offices, there are probably needier and more disenfranchised populations not represented by this survey. Also, given the fluctuations in insurance status that occur with time,[31] the associations with insurance status we found are probably subject to a conservative bias.

It should be noted that the proportion of variance explained by the models for perceived ease of access was modest (in the range of 10% to 20%) (Table 2) and consistent with previous results.[15] There was also a large amount of unexplained variation for the categorical access measures. Clearly, many other factors are important in gaining access to health care. Insurance is, however, probably the most easily altered factor, and the results of this study suggest that public insurance by no means solves the access problems it was meant to address.

In summary, in this relatively indigent population, we found uninsured persons to have the worst access, Medicaid recipients to be at an intermediate level of access, and people with private insurance to have the best access. Of particular concern is the finding that Medicaid recipients were even more likely than uninsured respondents to report being denied care. Controlling for insurance generally attenuated the effect of income, except for preventive services. Interactions suggested that poorer respondents more than 30 years of age may have more access difficulties than others after insurance status is controlled for. □

Cancer Incidence among American Indians and Alaska Natives, 1980 through 1987

ABSTRACT

Objectives. This study uses Indian Health Service inpatient data to estimate cancer incidence among American Indians and Alaska Natives.

Methods. Hospital discharge data for 1980 through 1987 were used to identify cases of cancer for 21 sites in women and 18 sites in men. Estimates of incidence were directly standardized to data from the Surveillance, Epidemiology, and End Results Program for the same time frame.

Results. Cancers of the gallbladder, kidney, stomach, and cervix show generally high rates among many American Indian and Alaska Native communities, and cancers of the liver and nasopharynx are high in Alaska. Of the relatively common cancers in Whites, American Indians and Alaska Natives experience lower rates for cancers of the breast, uterus, ovaries, prostate, lung, colon, rectum, and urinary bladder and for leukemia and melanoma. Variation among geographic areas and among tribal groups is observed for many important cancer sites.

Conclusions. This study demonstrates significant variations of cancer rates among American Indians and Alaska Natives, with important implications for Indian Health Service cancer control programs. The study also supports the potential use of hospital discharge data for estimating chronic disease among diverse American Indian and Alaska Native communities. Introduction

Cancer incidence rates in American Indian and Alaska Native populations are generally considered to be lower than those in the general US population,[1–3] largely on the basis of regional studies from the New Mexico Tumor Registry,[2,4] Montana,[5] western Washington state,[6] northwestern Ontario,[7] Manitoba,[8] British Columbia,[9] and New York.[10] However, studies of cancer among Alaska Natives have shown generally higher rates,[11,12] and investigators in western Washington and Montana have found that tumor registry data systematically underestimate cancer rates in American Indians because of misclassification of numerator data.[5,13] Faced with the need to plan rational cancer control programs for a wide spectrum of American Indian and Alaska Native communities, the Indian Health Service requires a better understanding of variations in cancer rates among different populations. Unfortunately, no single study has examined cancer incidence rates across a broad cross section of US American Indian and Alaska Native populations using methods that compare rates in these populations with those in the general population or compare rates among groups of American Indians and Alaska Natives. Scattered reports from specific communities, however, suggest higher rates for certain cancer sites[5,7,10–12,14] and the strong possibility of substantial variation in rates among these populations, due in part to ethnicity, genetic stock, geography, and cultural and behavioral factors.[12,15–18]

This study examined hospital discharge data maintained by the Indian Health Service to describe the burden of cancer by sex and site for the areas covered by the service and for nine major tribal groups. Although discharge data are not population based and do not necessarily capture all incident cases presented to the health care system, they are readily available and potentially useful for surveillance of chronic disease. This study explored the use of discharge data for estimating cancer rates; thus, it represents an important beginning to the systematic study of cancer and its variation among

American Indian and Alaska Native communities.

Background

A review of the literature of cancer in American Indians and Alaska Natives produced 22 nonduplicated, original reports of population-based studies conducted since 1970.[4–11,14,18–29] The results illustrate the variation in morbidity and mortality observed among different American Indian and Alaska Native populations studied to date. No population-based study has described cancer incidence in these populations with more than a regional scope.

The Indian Health Service provides direct care to approximately 1.1 million eligible American Indians and Alaska Natives.[30] The basic unit of operation for local health programs is the service unit, which integrates primary care and public health functions for a defined population and arranges for needed health care services not available in the local facility to be provided through contracts with providers in nearby metropolitan areas. The Indian Health Service operates 127 service units, with most located in the West and in Alaska. Of these units, 52 are operated by the local tribal authority on contract from the service. The Indian Health Service operates 43 hospitals, with another 7 operated by individual tribes. Management of the service units is coordinated by the following 12 regional administrative units, called Indian Health Service areas: Alaska, Albuquerque (New Mexico), Aberdeen (North Dakota, South Dakota, and Nebraska), Billings (Montana and Wyoming), Bemidji (Minnesota, Michigan, and Wisconsin), Portland (Oregon, Idaho, and Washington), Nashville (11 states east of the Mississippi River), Navajo (portions of Arizona and New Mexico), Oklahoma (Oklahoma, Kansas, and Texas), Phoenix (Arizona, Utah, and Nevada), Tucson (southern Arizona), and California. Hospital and outpatient care is also provided through contracts with local providers in instances in which service units are unable to provide needed services.

Methods

The Data Set

The Indian Health Service Inpatient Data System captures a standard data set for each patient discharged from a service or contract facility. All service and contract hospitals report to the system, with the exception of those in California and seven hospitals operated by contract to the local tribal authority. The latter include four hospitals in Alaska, one in Mississippi, and two in Oklahoma. Within the Nashville area, this exception in reporting left only the hospital serving the Eastern Cherokee in North Carolina. Since the Eastern Cherokee were included in the analysis by tribal group, the Nashville area was omitted from the analysis of Indian Health Service areas. Similarly, the California area, with no reporting hospitals, was not included. Finally, the Tucson area data were analyzed with those of the Phoenix area, since the Tucson area serves fewer than 20 000 individuals who share demographic and cultural characteristics with the service population of the Phoenix area. Consequently, data were examined for the populations served by nine Indian Health Service areas. Data reported for calendar years 1980 through 1987 were used in this analysis.

Estimation of Incident Cases

An algorithm was developed and tested to examine the data set and appropriately attribute multiple discharges to a single individual by means of social security number, sex, date of birth, community of residence, and hospital record number. In order to reduce the number of prevalent cases erroneously considered to be incident cases, another algorithm was developed to remove cases involving a site-specific cancer diagnosis in 1980 and 1981 from the estimates of incident cases for the study period 1982 through 1987. Thus, an incident case during the study time frame was identified as one involving an individual who had a site-specific cancer diagnosis during 1982 through 1987 with no cancer diagnosis at the same site in 1980 or 1981.

Rates were computed by Indian Health Service area and by nine major tribal groups. Rates computed by area were based on counts of incident cases attributed to a given area based on coded community of residence. Incident cases were attributed to a tribal group on the basis of both tribal affiliation code and community of residence at the time of initial cancer diagnosis. Patients living beyond the geographic area of the tribal organization were excluded from the tribal-specific analysis to maintain consistency with the denominator estimates, which were also based on tribal affiliation and place of residence (as described below).

Cancer sites were included in the analysis if their rate in either sex (directly age adjusted to the 1970 US population) was greater than 10 per 100 000 person-years or if other published studies had suggested an American Indian or Alaska Native rate significantly different from that in the non-Indian population. Consequently, the analysis considered 21 specific cancer sites in women and 19 in men.

Several sources of systematic error were considered in the estimates of incident cases. First, as noted above, four hospitals in the Alaska area and two in the Oklahoma area did not report inpatient discharge data. The populations served by the units that included the six hospitals were therefore omitted both from numerator counts and from the estimation of the population at risk. Second, it was believed that members of two service populations in the Northwest (Puget Sound and western Oregon) used non-Indian Health Service facilities; thus, these populations were omitted from the numerator and denominator estimates for the Portland area.

Other sources of systematic error were identified, but specific adjustments could not be made. For example, it is generally believed that American Indians and Alaska Natives in the Oklahoma area have better access to employer-based coverage of health services outside the Indian Health Service system. Also, inpatient data may not reflect care for some cancer sites, and these inconsistencies may vary by area as a result of differences in access and use of services as well as regional variation in practice patterns for cancer. Finally, there are probable sources of random error in the data as well, including errors in coding and data entry, as considered below.

Estimation of the Population at Risk

The population served by the Indian Health Service consists of all American Indians and Alaska Natives living on or near their reservation or formal seat of tribal government; this population was estimated to be just above 1 million in 1987.[30] The Indian Health Service population is considerably younger than the general US population. At the time of the 1980 census, the median age of American Indians and Alaska Natives was 22.6, compared with 30.0 for the US population. Approximately 32% of American Indians and Alaska Natives were less than 15 years old, and 5% were more than 64 years of age, compared with 23% and 11%, respectively, for the US population.[30]

Estimates of the denominator populations used to compute area and tribal rates were based on Indian Health Service

Note. Rates have been directly standardized to the 1970 US population. ICD-9 = *International Classification of Diseases*, 9th edition; SEER = Surveillance, Epidemiology, and End Results Program.

population data derived by means of projection techniques from the 1980 census. Adjustments were made, however, to correspond to corrections required in the numerator estimates, as described above. Specifically, the service populations of the six units with hospitals not reporting to the data system (four in the Alaska area and two in the Oklahoma area) and the two units believed to be underused in the Portland area were omitted from the denominator populations.

For computation of tribal-specific rates, the population at risk was estimated from the number of individuals reporting a specific tribal affiliation in the 1980 census[31] and residing in counties overlapping traditional or current tribal land and in geographic proximity to the formal tribal government. The number of tribal members at risk were summed across the counties constituting the tribal area. For the Apache tribe, the Arizona communities of White River and San Carlos, as well as the New Mexico community of Mescalero, were aggregated. The Sioux consisted of the communities in North Dakota and South Dakota. The Tohono O'Odham/Pima consisted of the communities at Sells and Sacaton in Arizona. The Navajo consisted of the communities on the Navajo reservation in northwestern New Mexico and northeastern Arizona. The Eskimo, Aleut, and Athabascan were drawn from appropriate aggregations of the communities in Alaska. The Oklahoma Cherokee and Eastern Cherokee consisted of those individuals who resided in Oklahoma and North Carolina, respectively, and who identified themselves as Cherokee.

Computation and Comparison of Rates

Incidence rates for nine Indian Health Service areas and for nine major tribal groups were computed and directly adjusted by age and sex (in 5-year intervals) to the 1970 US population. Methods described by Armitage[32] were used to compute 95% confidence intervals for each rate, and rates were considered to differ if the confidence interval of one did not include the rates for the other. The principal analysis compared rates computed for nine Indian Health Service areas and nine major tribal groups with rates reported for US Whites in the Surveillance, Epidemiology, and End Results (SEER) Program during 1982 through 1987 (J. Hon[illegible], unpublished data, 1982–1987). A secondary analysis examined variation among the nine areas and the nine tribal groups.

Estimation of Error in the Data Set

In order to estimate the magnitude of random error in the data set, rates computed from the data set and from the New Mexico Tumor Registry were compared for the cancer sites and time frame used in this study. The tumor registry collects cancer cases from New Mexico and systematically includes American Indian and Alaska Native cases in Arizona reported by the Indian Health Service. This area is roughly equivalent to the areas of Albuquerque, Navajo, Phoenix, and Tucson. In the comparison, both tumor registry and inpatient data system cases were restricted to patients who resided in Indian Health Service areas within Arizona and New Mexico. A previous Indian Health Service Cancer Program study had corrected minor errors in the tumor registry data, largely involving racial misclassification of cases.

For comparison, rates from both data sets were adjusted by age and sex to the 1970 US population, and the rates from the Indian Health Service inpatient data system were compared with those derived from the tumor registry; the latter were considered the "gold standard." Ratios were constructed by dividing the Indian Health Service rate by the tumor registry rate. All ratios observed for both sexes fell within the range of 0.7 to 2.1, with 38.5% below and 53.8% above 1.0. The male and female ratios for all cancer sites combined were 0.96 and 0.85, respectively, and 88% of the site-specific ratios were between 0.70 and 1.25.

A second analysis was carried out to compare results reported here with the population-based studies reported by the New Mexico Tumor Registry for 1973 through 1981[4] and by Lanier et al. for 1969 through 1983.[11] Indirect standardization to the 1982 through 1987 SEER data for US Whites produced standardized incidence ratios that expressed the ratio of cancer cases observed to those expected if the study population experienced the same age- and sex-specific rates as the standard population. (Tables of the standardized incidence ratio for nine Indian Health Service administrative areas and nine major tribal groups are available on request from the authors.)

Results

The data set used in the analysis contained records of just over 700 000 discharges for the period from 1982 through 1987. There were 4387 cancer cases during the 1982 through 1987 time frame used to estimate incident cases.

Comparison with Rates in US Whites

Tables 1 and 2 show age- and sex-adjusted incidence rates for the aggregate Indian Health Service population and for the population served by each of the nine areas included in this study. The overall male and female cancer rates were significantly lower than the rates for US Whites. Men experienced increased rates of morbidity for cancers of the nasopharynx (1.5 per 100 000), kidney (8.4), and gallbladder (2.4), while women had an excess of cancers of the stomach (6.8), gallbladder (7.1), and uterine cervix (19.5). American Indians and Alaska Natives experienced lower rates for several cancer sites that occur with relative frequency in US Whites. Women had lower rates of breast, uterus, and ovary cancer; men had a lower rate of prostate cancer; and both men and women had lower rates of lung cancer, colon and rectum cancer, urinary bladder cancer, leukemia, and melanoma. In all Indian Health Service areas and for both sexes, with the exception of women in Alaska, the all-site rates were lower and ranged generally from 30% to 60% of the rates for US Whites.

Among women, several specific cancer sites were elevated relative to US White women. These included cancer of the nasopharynx (Alaska), stomach (Albuquerque and Navajo), gallbladder (Alaska, Navajo, and Phoenix), cervix (Aberdeen, Alaska, Albuquerque, Billings, Navajo, Oklahoma, and Phoenix), and colorectal, lung and bronchus, and kidney (Alaska). Among men, cancers of the nasopharynx, stomach, and liver were elevated in Alaska; gallbladder cancer was elevated in Navajo; and kidney cancer was elevated in Alaska and Navajo.

Consistent with the general belief of lower cancer incidence in American Indian and Alaska Native populations, a number of cancers were seen to be less common than in US White populations. Notably, many of the cancers that are relatively common in the general US population were observed to be lower in many Indian Health Service areas. Cancer of the lung and bronchus was less common among men in Aberdeen, Bemidji, and Billings and among both sexes in Albuquerque, Navajo, Oklahoma, Portland, and Phoenix. Cancers of both the breast and the corpus uterus were reduced among women in each of the nine Indian Health Service areas. Colorectal cancer

Note. Rates have been directly standardized to the 1970 US population. ICD-9 = *International Classification of Diseases*, 9th edition; SEER = Surveillance, Epidemiology, and End Results Program.

rates were lower than those of US Whites for both sexes in Aberdeen, Albuquerque, Billings, Navajo, Oklahoma, Portland, and Phoenix. Cancer of the prostate was significantly lower in each area. Bladder cancer was lower in both sexes in all areas, with the exception of women in Alaska and Bemidji. While not common among US Whites, melanomas, leukemias, and non-Hodgkins lymphomas were even less common in most Indian Health Service areas.

Tables 3 and 4 compare cancer rates among nine tribal groups with those of US Whites and the aggregate Indian Health Service population. Consistent with the comparisons by area, the all-site rates were lower than those for US Whites, with the exception of Eastern Cherokee women and the three tribal groups of Alaska. All-site rates were higher for Eskimo and Athabascan women, lower for Eskimo men, and not substantially different from those of US Whites for Athabascan men and Aleuts of both sexes. For the other tribal groups, however, the all-site rates were lower than those for US Whites, ranging generally from 30% to 50% for men and 40% to 60% for women.

Cancer of the nasopharynx exceeded US rates for both sexes in the Eskimo and Athabascan populations and among male Aleuts, and salivary gland cancer was excessive in Athabascan and Aleut women. Cancer of the stomach was elevated in Eskimo men and Navajo women. Colorectal cancer was high in Eskimo women, and liver cancer was elevated among Eskimos of both sexes and among Sioux women. Gallbladder cancer dramatically exceeded US rates for Apache, Eskimo, and Tohono O'Odham/Pima women and for Navajos of both sexes, with rates ranging from 4 to 20 times those for US Whites. Interestingly, there appears to be a relative female preponderance (relative to US Whites) among most of the tribal groups for gallbladder cancer. Cervical cancer was elevated among Apache, Tohono O'Odham/Pima, Navajo, Sioux, and Eskimo women, ranging from 2.8 to 4.6 times the rates for US White women. Tohono O'Odham/Pima rates of cancer of the corpus uterus exceeded those of US White women, although lower rates were observed among all other tribal groups, consistent with the pattern noted for the areas.

As noted in the analysis of rates by area, many cancer rates by tribal group were less than those of US Whites. With the notable exception of Athabascan women, breast cancer rates were reduced among all tribal groups, ranging from 18% (Tohono O'Odham/Pima) to 55% (Sioux) of the White rates. Cancer of the lung and bronchus was generally below US White rates, except for similar rates among Eskimos of both sexes, Sioux women, and Athabascan and Aleut men. Rates exceeded those for US Whites, however, among Athabascan and Aleut women.

Variation among Indian Health Service Areas and Tribal Groups

Considerable variation was observed both among areas and among tribal groups for cancers of the oropharynx, nasopharynx, stomach, colon and rectum, liver, lung and bronchus, breast, cervix, uterus, and kidney and for cancers of all sites. Within the pattern of variation, there were relatively high rates in Alaska and relatively low rates in the Oklahoma and Navajo areas, also reflected in the tribal groups of the region.

Knowledge of variation is useful to support rational planning, development of clinical policies, and resource allocation across the diverse communities served by the Indian Health Service. The magnitude of variation observed among American Indian and Alaska Native populations is often dramatic. Relative to US White men, cancer of the liver was experienced only 18% as often in Oklahoma men and 50% as often by men in Portland and Phoenix; however, these rates ranged to three times the US White rate in Alaska. Lung cancer rates were 13 to 14 times higher among Alaska and Bemidji women than among Navajo women. There was a twelvefold difference in colorectal cancer rates between Eskimo and Tohono O'Odham/Pima women, a twenty-threefold difference in prostate cancer rates between Apache and Eastern Cherokee men, a twelvefold difference in stomach cancer rates between Portland and Albuquerque women, and a seventeenfold difference in leukemia rates between Eskimo and Tohono O'Odham/Pima women.

Comparison with Other Studies

In order to examine the precision of the judgments made in this study, we compared standardized incidence ratios computed from our data (available from the authors on request) with those reported from the New Mexico Tumor Registry for 1973 through 1981[4] and from an Alaska population-based study for 1969 through 1983.[11] The studies from the tumor registry were compared with our data for the Albuquerque area, although the tumor registry includes a substantial population of Navajos whose reservation extends into northwestern New Mexico. The data from Alaska were compared with our findings for the Aleut, Athabascan, and Eskimo populations, permitting comparison of results at the tribal-specific level.

Of the 16 cancer sites with standardized incidence ratios suggesting variation from US Whites found for the Albuquerque area, all were confirmed by studies from the tumor registry. Of the 27 cancer site variations from US Whites suggested by the standardized incidence ratios for the three tribal groups in Alaska, Lanier[11] reported significant findings for 21 (78%) and reported an observed-to-expected ratio in the same direction (more or less than 1.0) in 25 (93%). Our data suggested elevations of cancer rates for lung and ovary in Athabascan women not found by Lanier, although she projected a possible increasing trend in lung cancer from her 1968 through 1983 time frame.

Conversely, of the 40 findings reported from the New Mexico Tumor Registry,[4] we found 38 (95%) with standardized incidence ratios in the same direction. Data from the tumor registry suggested lower rates for cancer of the ovary and esophagus in men that were not confirmed by our data. However, the tumor registry included a substantial number of Navajos, and our data report a decrease in esophageal cancer for both the Navajo area and the Navajo as a tribal group. A similar decrease in cancer of the ovary (standardized incidence ratio = 0.7) was observed in Navajos. Of the 43 significant findings reported by Lanier[11] for the three tribal groups in Alaska, we found 36 (84%) with standardized incidence ratios in the same direction. Lanier reported elevations for cancer of the salivary gland in Eskimo women, cancer of the nasopharynx in Aleut women, cancer of the esophagus in Eskimo men, cancer of the gallbladder in Athabascan women, and multiple myeloma in Athabascan men, as well as a decrease in breast cancer in Athabascan women, that were not found in our data.

Discussion

This study confirms the impression of generally lower cancer rates among American Indians and rates among Alaskan Natives that approach those of the US general population. More important, however, is the demonstration of dramatic variation in cancer burden within the Indian Health Service population, as noted for leukemia, stomach, liver, lung, prostate, and colorectal cancers. These find-

ings underscore the danger inherent in generalizing health issues across the many distinct American Indian and Alaska Native communities and tribal groups.

Substantial variation may also be observed within an Indian Health Service area that is only apparent on tribal-specific analysis. For example, in the Phoenix area, cancer of the uterus is elevated among Tohono O'Odham/Pima women but lower among Apache women, with the elevation in the former not reflected in the relatively low rates for the Phoenix area. Cancers of the gallbladder and uterine cervix are consistently elevated across a broader range of Indian Health Service areas and tribal groups, and they appear to exceed US White rates in one or both sexes in Aberdeen, Alaska, Albuquerque, Navajo, Portland, and Phoenix. Nonetheless, variability in rates across areas is also apparent, with rates that cannot be distinguished from those of US Whites in Bemidji, Billings, and Oklahoma and rates that range upward to a tenfold elevation among women of Alaska and Phoenix.

Some caution is in order in interpreting the rates reported from this study. Discharge data probably underestimate some cancers that do not require hospitalization, and underuse of the Indian Health Service system may result in low estimates of community cancer care. The degree of underestimation may also vary by Indian Health Service area and by tribal group as a function of local service use and practice patterns. Finally, many of the incidence rates reported are based on relatively small numbers when disaggregated to the area or tribal level. Multiple comparisons are also a legitimate concern whenever so many different associations are considered. Nonetheless, the findings are useful in generating hypotheses for more detailed studies that could link Indian Health Service data with state cancer registry and vital data.[5]

For several cancer sites, further research would be particularly important to support cancer control programs. First, invasive cervical cancer rates exceed US rates in six Indian Health Service areas (ranging to 3.8 times the US rate in Alaska and Billings) and appear to actually exceed breast cancer rates in the Albuquerque and Phoenix areas. Prevention of invasive cervical cancer is well within the state of the art, and several research and demonstration projects are currently under way in the Indian Health Service to increase participation in cervical cancer screening programs. Cancer of the uterine corpus is elevated in Tohono O'Odham/Pima women and appears to be due to an excess of endometrial cancer. This finding has been discussed previously (J. Justice, unpublished data, 1974), and it certainly deserves more careful study to confirm the elevated rate and to examine potential risk factors. If the excess is confirmed, a program to alert women to the danger signs and need for screening would be appropriate. Dramatically elevated rates of cancer of the gallbladder are apparent in many American Indian and Alaska Native populations and have been shown to be associated with the presence of gallstones.[21,33,34] While standard screening procedures have not been tested for this cancer, the relatively high rates and generally poor outcome may stimulate research on strategies for prevention or early detection. It is interesting to speculate on the observation of no excess gallbladder cancer in two Cherokee populations that have been geographically separated for many generations. If confirmed by further study, this finding might provide the opportunity to study the relative effect of genetic and environmental factors on gallbladder cancer.

Cancer of the lung and bronchus has generally been lower among American Indians and Alaska Natives, presumably as a result of a nonsmoking tradition among many of these populations. Even so, lung cancer continues to be the most frequent cancer among American Indian and Alaska Native men and the fourth most frequent among women, trailing breast, colorectal, and cervical cancer. Moreover, our data suggest that lung cancer rates in women in Billings, Aberdeen, and Bemidji approach those of their White counterparts. Most alarming, however, is the evidence of high smoking rates among American Indian and Alaska Native adolescents[35] and young adults.[36,37] Programs targeting smoking cessation continue to be one of the most important cancer prevention strategies.

More difficult policy challenges confront the Indian Health Service in regard to several cancers that are less common in American Indian and Alaska Native communities, but for which current screening recommendations are based on the higher baseline rates of the general US population. In the face of the considerable deterioration in performance of screening tests that accompany lower population rates and the large number of serious health problems among American Indian and Alaska Native communities competing for limited health care resources, it is not clear that such recommendations should be applied uniformly. For example, rates of breast cancer in most Indian Health Service areas range from 18% to 50% of those in Whites. A recent Indian Health Service study examined the dramatically increased cost per breast cancer death prevented by screening mammography programs as a result of the relatively low incidence levels common to American Indian and Alaska Native populations.[38] A similar paradox exists in the cases of colorectal and prostate cancer, for which rates in many American Indian and Alaska Native communities are generally substantially lower than those in the US population. Coupled with substantial intertribal variation, such deviation from the rates of the US White population further stresses the need to match cancer control strategies to the rates observed in individual communities. The availability of better information on cancer incidence by community affords the opportunity to plan locally appropriate and cost-efficient methods for cancer surveillance.

Based on comparisons with existing studies of cancer in American Indian and Alaska Native populations, the Indian Health Service inpatient data set appears to be useful in estimating the variation of cancer incidence between these populations and US Whites and across relevant subsets of the service population. Several analyses have been conducted that support improvements in the quality of the data (S. Valway, unpublished data, 1989).[5,39] Similar rates and sources of error have been demonstrated in studies of cancer using discharge data in other settings as well.[40,41] Hospital discharge data, nonetheless, are generally believed to be useful for cancer surveillance,[40-42] particularly when accompanied by efforts to improve their quality.[43,44]

Summary and Conclusions

This study has demonstrated dramatic variation in cancer rates among the Indian Health Service areas and among nine major tribal groups. Such variation underscores the diversity among American Indian and Alaska Native groups and the need to target cancer control programs as a function of the epidemiology of preventable cancer. The impression that cancer rates are generally lower among American Indian and Alaska Native communities in the Southwest and that these rates approach those of US Whites in Alaska is generally confirmed. Rates among Eastern Cherokee women, however, also appear to approach those of

US Whites. Cancers of the gallbladder, stomach, and cervix show generally high rates among many American Indian and Alaska Native communities, and cancers of the liver and nasopharynx are high in Alaska. Conversely, several cancer sites that are relatively prevalent among US Whites (e.g., cancers of the breast, ovary, and uterus in women; prostate cancer in men; and colorectal cancer, lung and bronchus cancer, urinary bladder cancer, leukemia, and melanoma in both men and women) are less common. Finally, this study suggests that Indian Health Service inpatient data are useful in hypothesis-generating studies of rates and variations among American Indian and Alaska Native populations for chronic disease but that further attention to their quality may be necessary if they are to serve as an effective surveillance system. □

Acknowledgments

The work reported here was accomplished with funding from the National Cancer Institute (grant Y02-CN-90667) and the Office of Planning Evaluation and Legislation of the Indian Health Service.

We would like to thank our project officers, Drs Gregory Christenson and John Horm of the National Cancer Institute and Ramona Ornelas, Office of Planning Evaluation and Legislation, Indian Health Service, for their professional assistance and encouragement.

Improving Response Rates through Incentive and Follow-Up: The Effect on a Survey of Physicians' Knowledge of Genetics

ABSTRACT

Objectives. This study assessed efforts to increase response rates to a mailed physician survey and examined whether, as a result, nonresponse bias was reduced.

Methods. Randomly selected physicians and geneticists were mailed a questionnaire concerning genetics knowledge and attitudes. In the final but not the pilot survey, a $25 incentive and intensive follow-up were used to increase the response rate.

Results. The response rate from physicians in the final survey was 64.8% (n = 1140), compared with 19.6% in the pilot test (n = 69). Sample representativeness in sociodemographic and practice characteristics was improved by follow-up. Respondents recruited with more difficulty did not differ on the principal outcome variable, genetics knowledge, except on one subscore. Pilot study and final survey respondents did not differ in knowledge.

Conclusions. Although the effect of increased response rates on the principal outcome variable in this study was minimal, this may not be the case for other studies. Every effort should be made to attain as high a response rate as is practical and to establish that respondents are representative of the population being sampled. Introduction

Findings from surveys in which response rates are low are open to the criticism that they do not represent the entire population sampled. Increasing response rates may not, however, reduce nonresponse bias if the additional respondents resemble those easily recruited more than they resemble the remaining nonrespondents.[1–3] Differences between respondents and nonrespondents can still be found with moderately high (60% to 70%) response rates.[1,4] Others have concluded that with response rates of 75%, the bias introduced by differences between respondents and nonrespondents may be minimal.[5]

We obtained very low response rates in pilot testing a survey of physicians' knowledge and attitudes regarding human genetics. Consequently, extensive measures were taken to increase the response to the final survey, and a much higher response rate was achieved. This paper describes the steps taken to increase responses and examines whether the increase minimized response bias and affected the outcome variables of interest. Three questions were investigated: (1) Were there significant differences between respondents and nonrespondents to the final survey in sociodemographic and practice characteristics? (2) Did follow-up measures that brought in additional respondents improve sample representativeness and therefore alter the primary outcome variables? and (3) Did respondents to the final survey differ from pilot test respondents in their responses to the outcome variables? The answers to these questions have implications for choosing a cost-effective approach to surveying physicians. If respondents recruited with greater difficulty resemble other respondents more than they resemble nonrespondents and do not, therefore, reduce response bias, incentives and follow-up aimed solely at increasing response rates may not be effective.

Methods

Pilot Test

A questionnaire was developed by our team of geneticists and behavioral scientists. Revisions were made after each of two pretests, the first involving two local genetic counselors and four medical geneticists and the second involving a panel of 10 local primary care physicians.

The resulting questionnaire was pilot tested on a national sample consisting of 72 each of family physicians, internists, obstetrician-gynecologists, pediatricians, and psychiatrists. (From this point on, "physicians" refers to the above specialties but not to geneticists.) Physicians were randomly selected from the American Medical Association Physician Masterfile. Because we were more interested in determining what is currently being taught in medical schools, physicians in each specialty who graduated from medical school between 1971 and 1985 were sampled in a ratio of 2:1 relative to those who graduated between 1950 and 1970. sample of 72 board-certified geneticists and genetic counselors was randomly selected from lists provided by the American Board of Medical Genetics.

The questionnaire was mailed to physicians accompanied by a letter from the principal investigator and a letter of support from the American Medical Association. In addition, letters of support were enclosed from the American Academy of Family Physicians, the American College of Physicians, the American Society of Internal Medicine, the Society of Perinatal Obstetricians, and the American Academy of Pediatrics in the mailing to physicians in the corresponding specialty. The geneticists' questionnaires were accompanied only by a letter from the principal investigator. Subjects were assured that after data collection was complete, their responses would be anonymous. A postcard reminder was mailed to all nonrespondents 2.5 weeks after the questionnaire mailing. The data collection process lasted approximately 2 months.

In order to assess the usefulness of offering 10 American Medical Association category 1 continuing medical education credits in the final survey as a response incentive, a random sample of half of the physicians in each specialty in the pilot sample were offered such credits for completing the questionnaire.

Final Survey

Questionnaire. The questionnaire was revised on the basis of an analysis of the pilot survey. The final version of the questionnaire could be completed by physicians in approximately 30 minutes. All questions, except for certain demographic questions, were in multiple choice format. Demographic, genetics knowledge, and opinion questions, as well as two psychometric scales, were included. It was the consensus of the developers that respondents who answered the knowledge questions correctly would be capable of explaining test results to their patients. A detailed description of the knowledge questions appears elsewhere,[6] and other analyses are in preparation.

Sample. The physician sample for the final survey was also selected from the American Medical Association Physician Masterfile. Physicians in only 10 states were sampled to make it easier to gain the help of local chapter chairs of medical specialty societies in improving response rates. One state was randomly selected from each of the 10 genetics network regions established by the Health Resources Administration of the US Department of Health and Human Services. The 10 states were New York, Illinois, Nebraska, Pennsylvania, Utah, Maine, Oregon, California, South Carolina, and Texas. Sampling in New York and California was limited (by random selection) to upstate areas and greater Los Angeles, respectively, in order to include only one chapter area per state for each specialty society. Physicians in each specialty were sampled in equal numbers from each state. In each state, physicians within each specialty who graduated between 1971 and 1985 were sampled in a ratio of 2:1 relative to those who graduated between 1950 and 1970. Participation was invited only from members or candidate members of the following societies (as determined by a search of the societies' directories): American Academy of Family Physicians, American College of Physicians, American College of Obstetricians and Gynecologists, American Academy of Pediatrics, and American Psychiatric Association. The final sample included 1795 physicians. (358 family physicians, 360 internists, 360 obstetrician-gynecologists, 359 pediatricians, and 358 psychiatrists). For comparison, 180 medical geneticists and 180 genetic counselors in the same 10 states were sampled from membership lists provided by the American Board of Medical Genetics. For states with 18 or fewer medical geneticists or genetic counselors, all names were selected. For the remaining states, 18 medical geneticists and 18 genetic counselors were randomly selected. For each state with fewer than 18, one geneticist was selected from each of the states with a surplus until 18 had been sampled.

Response incentives. Two incentives were offered to all physicians. First, respondents were offered a check for $25 on return of the completed questionnaire. Second, except for family physicians, respondents were offered 10 American Medical Association category 1 continuing medical education credits for completing the questionnaire and agreeing to review additional information sent afterward. The American Academy of Family Physicians agreed to award 7 prescribed continuing medical education credits to family physicians for the same activities. The prescribed credits are valuable to family physicians in terms of recertification.

Administration and follow-up. A number of additional measures were taken to achieve response rates for physicians higher than those obtained in the pilot test. Chapter chairs of the American Academy of Family Physicians, the American Academy of Pediatrics, and the American Psychiatric Association co-signed, with the principal investigator, the letter that accompanied the questionnaire to physicians in their chapters and also signed a postcard reminder. In some instances, the chapter chair included a personal note with the letter. The American College of Physicians agreed to have its president cosign the letters to internists. Consistent with its policy of limiting access to its membership for survey purposes, the American College of Obstetricians and Gynecologists declined to participate. Consequently, the president of the Society of Perinatal Obstetricians agreed to cosign all cover letters to obstetricians. As in the pilot study, subjects were assured that their responses would remain anonymous.

An "alert" postcard preceded the questionnaire mailing to physicians by 3 working days. Follow-up included a postcard reminder, phone calls from a survey research firm 2 weeks after the initial mailing, a second questionnaire mailing to physicians in specialties with response rates lower than 55% (family physicians, internists, and obstetricians), and a final round of phone calls to these physicians. Because no difficulty was anticipated in obtaining an adequate response from medical geneticists and genetic counselors, incentives were not offered to these subjects, and follow-up was limited to a postcard reminder. The entire data collection process lasted approximately 4.5 months.

Results

Response Rates

Questionnaires that for some reason did not reach the intended respondent (i.e., death, retirement, relocation) were not included in calculations of response rates. The average response rate for the pilot test from physicians was 19.6%. The highest response was from pediatricians, and the lowest rate was from obstetricians. A much higher response (74.6%) was obtained from geneticists (Table 1). With the exception of family physicians, the offer of continuing medical education credits did not affect the likelihood of response.

Physician response rates in the final survey were significantly higher than those in the pilot test (Table 1). The overall response rate for physicians was 64.8%. Again, the response from pediatricians was greater than from other specialties,

and a high response rate (79.1%) was achieved for geneticists.

Respondents vs Nonrespondents: Final Survey

Information included on the American Medical Association Physician Masterfile was used to compare physician respondents and nonrespondents in the final survey by chi-square analysis. Six of eight demographic and practice variables differed significantly at $P < .05$ (Table 2). Respondents were more likely than nonrespondents to be younger than 40, to have graduated from US medical schools, to have graduated from medical school after 1977, and to be board certified; they were less likely to be in practice by themselves. Pediatricians were more likely to respond than physicians in other specialties. For variables that showed a significant difference overall between respondents and nonrespondents, the trend remained the same when analyzed by specialty, although the level of significance varied.

A logistic regression with respondent vs nonrespondent as the dependent variable was performed to adjust for confounding among the practice variables. Attending a US rather than foreign medical school was the most important predictor, with US medical school graduates being more than twice as likely to respond as foreign medical graduates (OR = 2.158, $P < .0001$). Year of graduation, specialty, and board certification were independently related to the likelihood of response. Other variables were not significant.

Effect of Additional Respondents on Sample Representativeness

Of the physicians, 23.5% responded within 3 working days of the postcard reminder mailing ("early" group) and 18.8% responded within 5 days of the first telephone follow-up ("middle" group). An additional 22.5% responded before termination of data collection ("late" group).

Comparisons by length of time taken to return the questionnaire are presented in Table 3. Significant differences between early, middle, and late respondents were found for several demographic and practice variables. A stepwise multiple regression with number of days to respond as the dependent variable was performed to adjust for confounding among the variables associated with response time. Specialty, US medical school, race, and importance of attending religious services accounted for 6% of the variance in response time. Academic appointments did not enter the regression equation.

No differences were found between early, middle, and late respondents on questions related to genetics training and experience and attitudes toward genetics. An overall genetics knowledge score was created by assigning one point for each correct answer (one 4-part question was assigned one-fourth point for each correct answer), for a possible total score of 26. Concepts (maximum score = 17) and facts (maximum score = 9) subscores were also computed.[6] The overall score

Total	19.4 ± 3.6	19.1 ± 3.6	18.9 ± 3.6	1.83

[a]$P = .01$.

did not differ significantly by response time. However, late respondents scored significantly lower than early respondents on the concepts subscore (Table 4). A hierarchical multiple regression with the concepts score as the dependent variable was performed to determine whether response time was independently related to the concepts score. Specialty, US vs foreign medical school attendance, academic appointments, and race, entered as predictors in block 1, accounted for 12.3% of the variance in the concepts score. Response time, entered in block 2, accounted for an additional 0.4% ($P < .05$) of the variance in the concepts score after the other variables had been entered.

Pilot Test vs Final Survey Respondents

Respondents to the pilot test were more likely than were final survey respondents to state that it is important (51.5% vs 43.5%) or extremely important (47.1% vs 39.3%) to attempt to detect actual or potential genetic disorders (chi-square test, $P = .0002$). Scores designed to compare the knowledge of physicians who responded to the pilot test and the final survey were created by totaling the number of correct responses for 20 knowledge questions (12 concepts questions and 8 facts questions) appearing on both the pilot test and final questionnaires. Neither the overall knowledge score nor the two subscores differed significantly between pilot test and final survey respondents. However, obstetricians in the pilot test scored almost two points higher in overall knowledge than those in the final survey. This difference was not statistically significant because of the small number of obstetricians in the pilot test. Obstetricians in the pilot test did not differ significantly from geneticists in knowledge.

Discussion

The dramatic increase in the physician response rate from the pretest to the final survey is attributable to a combination of incentives and follow-up. As has been shown previously in surveys of physicians,[4,7] the monetary incentive was an important factor. The offer of continuing medical education credits was not as effective overall but contributed to the response rate of family physicians, for whom such credits are important for recertification. Repeated follow-ups elicited a gradual increase in response. In summary, response rates can be improved in

mail surveys of physicians when incentives and persistent follow-up are used.

Certain groups of respondents were more difficult to recruit. Foreign medical school graduates were less likely to respond than were US graduates, as has been found in previous research.[1] With protracted efforts, a higher proportion of responses from foreign medical school graduates was obtained. Therefore, follow-up did improve sample representatives. Nevertheless, differences between respondents and nonrespondents in sociodemographic and professional characteristics remained. Although statistically significant, these differences were relatively small in magnitude. In surveying physicians, efforts should be directed at obtaining responses from groups that are typically difficult to recruit, such as foreign medical school graduates.

For pilot test respondents, the perceived importance of detecting genetic disorders was higher than for respondents to the final survey. In the absence of incentives, we believe that respondents to the pilot survey were more likely to be motivated by belief in the importance of genetics than were nonrespondents. This can contribute to response bias, as was probably the case for obstetricians in the pilot test whose knowledge scores were not significantly different from those of geneticists.

Changes in response rates in the final survey had minimal impact on the primary dependent variable of genetics knowledge. A small difference between early and late respondents was found for one knowledge subscore. Although the effect of increased response rates on the principal outcome variable in this survey was minimal, this may not be the case in studies of other topics. Therefore, every effort should be made to attain as high a response rate as is practical and to establish that respondents are representative of the population being sampled. □

Acknowledgments

This work was supported by grant R01-HG00026 from the National Center for Human Genome Research, National Institutes of Health, and by a grant from the American Medical Association Education and Research Foundation.

We are grateful to Sidney Hollander and Patricia Linzey for their advice on questionnaire construction and to them and their staff for assistance in improving the response ratio. Sharon Ennis provided invaluable assistance in organizing the mailing and typing questionnaires, tables, and manuscripts.

Weapon Carrying among Inner-City Junior High School Students: Defensive Behavior vs Aggressive Delinquency

Daniel W. Webster, ScD, MPH, Patricia S. Gainer, JD, MPA, and Howard R. Champion, MD

ABSTRACT

Objectives. The purpose of this study was to estimate associations between beliefs and experiences hypothesized to be related to weapon carrying among youths.

Methods. Students in two inner-city junior high schools completed anonymous questionnaires. Logistic regression models were fit for having ever carried a weapon for protection or use in a fight and were stratified by sex and weapon type.

Results. Among males, 47% had carried knives and 25% had carried guns. Key risk factors for knife carrying were being threatened with a knife, getting into fights, and disbelief that having a weapon increases the carrier's risk of injury. Gun carrying was associated with having been arrested, knowing more victims of violence, starting fights, and being willing to justify shooting someone. Among females, 37% had carried a knife; knowing many victims of violence and being willing to justify shooting someone predicted knife carrying.

Conclusions. Knife carrying was associated with aggressiveness but did not appear to be related to serious delinquency. Gun carrying within this nonrandom sample appeared to be a component of highly aggressive delinquency rather than a purely defensive behavior. (*Am J Public Health.* 1993;83:1604–1608)

Introduction

Weapon-related violence is a major health problem among adolescents in the United States. Homicide is the second leading cause of death for youths aged 15 through 19 years. Almost half of the Black males aged 15 through 19 who died in the United States in 1989 were murdered, typically with a gun.[1] Of the 2771 homicide victims aged 10 to 19 years in 1989, 80% were killed with guns and 10% were stabbed to death.[1] Firearm homicide rates for Black males aged 10 through 19 years increased by 140% from 1979 to 1989.[1,2]

Youths are often perpetrators of violence as well as its victims. Nationwide, 17% of all persons arrested for violent crimes in 1991 were younger than 18 years of age.[3] Juvenile arrests for serious violent offenses have increased dramatically since the mid-1980s; these increases have coincided with a sharp rise in juvenile arrests for weapon carrying.[4]

A higher incidence of gun carrying among youths has been implicated as a key factor contributing to recent increases in youth violence.[4] National survey data on high school students revealed a monthly prevalence of weapon carrying of 20% in 1990.[5] Weapon carrying prevalence was highest among Black (39%) and Hispanic (41%) males. Twenty-one percent of Black males reported that they had carried a gun over the past month. A recent survey conducted in 10 selected inner-city high schools in four states found that 35% of male students and 11% of female students reported carrying a gun.[6]

Because weapon carrying can increase risks both to the individual carrying the weapon[7,8] and to others,[9] reducing weapon carrying among adolescents is among the national health objectives for the year 2000.[10] Yet little is known about the determinants of weapon carrying among adolescents. Data from a survey of inner-city high school students in the Midwest[11] and a focus group study in Dade County, Florida,[12] suggest that gun carrying is motivated by a belief that carrying a gun provides protection against being "jumped." Other studies have found weapon carrying among youths to be highly correlated with serious criminal activities.[6,13,14]

In the present study we assess the relationship between weapon carrying and a variety of personal factors hypothesized to be related to weapon carrying within a nonrandom sample of students attending two public junior high schools in Washington, DC. Weapon carrying was hypothesized to be a function of seven related factors: (1) first- and second-hand exposure to violence; (2) delinquent activities; (3) beliefs about the acceptability of hitting someone under certain conditions; (4) beliefs about the acceptability of shooting someone under certain conditions; (5) perceived peer support of violence; (6) aggressive behavior patterns; and (7) the belief that having a weapon can provide effective protection against an attack.

Methods

Study Participants and Data Collection

As part of a larger study to evaluate the effects of a youth violence prevention program, baseline data were collected in two public junior high schools in Washington, DC. In school A, seventh-grade students enrolled in compulsory drug education classes were surveyed in the spring and fall of 1991. Students in school B were enrolled in eighth-grade social studies classes and were surveyed in the fall of 1991. School A is located in the central part of the city, an area that has a relatively high crime rate. School B is located in the southeastern part of the city, which has the highest concentration of poverty and crime. More than 95% of the students in each school were Black.

Students were instructed not to write their names on the questionnaires to protect the anonymity of their responses and were assured that only the research team would see their responses. In the classroom, as students read and completed the questionnaires, each question was read aloud by a member of the research staff.

Measures

The prevalence and frequency of weapon carrying was assessed with two sets of nested questions. For both guns and knives, students were asked, "Have you ever carried a gun (knife) with you for protection or to use in case you get into a fight? If your answer is yes, how many times would you say that you carried a gun (knife) for protection during the past 2 weeks?"

Three of the hypothesized risk factors for weapon carrying were measured by scales. The Hitting Acceptable scale was based on the sum of three attitudinal items, each with a 6-point Likert-scale response indicating level of agreement or disagreement with a statement pertaining to circumstances under which hitting someone was justified. The Shooting Acceptable scale was the sum of the responses to two items concerning conditions under which shooting someone was believed to be justified. A third scale, Image/Norms, included six items related to concerns about self-image and perceived peer norms pertaining to aggression. The internal consistency of these attitudinal scales was generally good (Hitting Acceptable $\alpha = .74$, Shooting Acceptable $\alpha = .55$, Image/norms $\alpha = .78$).

Data Analysis

Bivariate associations between ever having carried a weapon and dichotomous independent variables were measured by unadjusted odds ratios for which 95% confidence intervals were calculated. Differences in means for continuous independent variables were assessed by means of Student's t test.

Logistic regression analysis was used to assess the effects of each independent variable while controlling for other variables in the models. Interaction terms were included in the model if there was some theoretical rationale for the interaction and if the Wald statistic for the term was significant at the .05 level.

Three measures of model fit were used: the deviance statistic (D), the Pearson chi-square goodness-of-fit statistic (GOF χ^2), and Hosmer and Lemeshow's G^*_y statistic.[15,16] Model coefficients, B_i, were transformed (e^{Bi}) so that they could be interpreted as adjusted odds ratios, and 95% confidence intervals were calculated for each e^B. Each variable's contribution to the prediction of weapon-carrying status was measured by the partial correlation coefficient R.

Results

Profile of Respondents

Data on knife or gun carrying were available for 294 of the 295 respondents, all of whom were Black. Compared with respondents in school B, school A respondents were 1 year older on average (mean = 14.2 years, range = 12.9–16.7, vs mean = 13.3 years, range = 11.1–16.0; $t = 5.78$, $P < .001$) and somewhat less likely to live with their father or stepfather (27% vs 39%, $\chi^2 = 2.23$, $df = 1$, $P = .14$).

Prevalence and Frequency of Weapon Carrying

Nearly half of the males reported carrying knives for protection or to use in case they got into a fight (Table 1). The prevalence of ever carrying a gun among males was 23% in school A and 40% in school B. Knife carrying was also more prevalent among females in school B (67%) than in school A (31%).

Because the difference in the frequency of weapon carrying between schools among those who reported they had carried a weapon was not statistically significant, frequency data were combined across schools (Table 2). One of every five knife carriers carried a knife on a routine basis (from 8 through 14 days during the previous 2 weeks), whereas 16% of male gun carriers carried guns routinely.

TABLE 1—Percentage of Students Reporting Ever Having Carried a Weapon for Protection or for Use If in a Fight, by Sex, Grade, and Weapon Type

Females	15	7	53	25	11	5	21	10
Carried gun								
Males	26	10	37	14	21	8	16	6

Bivariate Associations

Among males, having been arrested, having been threatened or attacked with a weapon, and getting into fights were all associated with increased odds of having carried a knife (Table 3). Lack of belief that weapon possession increases one's risk of being injured or killed, evident in 55% (87/157) of male respondents, was associated with knife carrying. Compared with other males, those who had carried knives knew more people who had been injured or killed by violence (mean = 6.7 vs 4.2, $t = 2.08$, $P = .04$). Males who carried knives had higher scores on the Hitting Acceptability scale ($t = 2.92$, $P = .004$), but did not differ from other males on either the Shooting Acceptability scale ($t = 0.33$, $P = .74$) or the Image/norms scale ($t = 1.55$, $P = .12$).

The same general pattern of bivariate associations with knife carrying emerged for females and males; however, these associations were somewhat stronger for females (Table 4). The exception to this pattern was a lack of association between knife carrying and belief that having weapons increases one's risk of being injured or killed. On average, females who carried knives knew more than twice as many victims of violence as did other females (mean = 7.9 vs 3.5, $t = 4.85$, $P < .001$). In addition, females who carried knives had higher scores on the three attitudinal scales.

The odds of ever having carried a gun were 7.7 times higher among males with an arrest history (weapon-carrying offenses excluded) than among males who had never been arrested (Table 5). All nine males who had been arrested for drug violations reported having carried a gun. A tendency to fight, including starting fights, was also related to having carried a gun, as was having been threatened or attacked with a gun. Males who carried guns knew more victims of violence than did males who did not carry guns (mean = 9.53 vs 4.44, $t = 2.82$, $P = .007$). Gun carriers also had higher scores on all three attitudinal scales.

Multivariable Analysis

The adjusted odds ratios derived from the logistic regression models for having carried a knife are presented in Table 6. For males, the strongest predictors for having carried a knife were having been threatened or attacked with a knife, disbelief that having weapons increases injury risks, and being more likely than classmates to get into fights but not usually being the one to start fights.

Estimates from the model for having carried a knife were markedly different for females. The 95% confidence limits for the adjusted odds ratios for only two predictors did not include 1.0. Belief in the acceptability of shooting someone under certain circumstances was the strongest predictor of knife carrying among females. After the other factors in the model were controlled for, each additional victim of violence known by the respondent was associated with a 19% increase in the odds of knife carrying.

Having been arrested was the single best predictor of having carried a gun for males (Table 7). The odds of having carried a gun were considerably elevated among males reporting the most aggressive behavior patterns (i.e., being more likely than classmates to participate in and to initiate fights). Believing that shooting someone is justifiable under certain circumstances and perceiving peer acceptance of violence were also positively associated with gun carrying. After other factors in the model were controlled for, neither having been threatened or attacked with a gun nor disbelief that having

a weapon increases injury risk was significantly related to gun carrying. (Note: One case was removed from the model because of the extreme effect it had on the estimates and the model's fit. The case removed was a respondent who reported having carried a gun, but had never been arrested or threatened with a gun, and who was less inclined to get into or start fights. Removing this case improved the fit of the model dramatically. For example, the G^*_y for the model with the outlier was 25.10 (df = 11, p = .01) compared to 4.96 (df = 11, p = .93) without the outlier. Most estimates increased when the case was removed.)

Discussion

Weapon carrying was alarmingly common among this convenience sample of inner-city seventh- and eighth-grade students. Our findings indicate that risk factors for weapon carrying varied by sex and weapon type. Among males, knife carrying was strongly related to aggressive behavior tendencies and the belief that having a weapon does not increase one's risk of being injured by violence. Having been threatened or attacked with a knife was an important predictor of knife carrying among males. This may be more indicative of respondents' propensity to get into fights with others who carry knives than of random victimization.

The beliefs and behaviors of males who carried knives tended to be aggressive; unlike gun carriers, however, they were not at the outer extremes on these measures. Gun carrying was also strongly linked with indicators of serious delinquency. Most males who had been arrested had also carried a gun and all who had been arrested on drug-related charges had carried a gun. The associations between gun carrying and the number of victims of violence known, and the perception of peer support for violence, suggest that gun carrying is partially determined by the degree to which a youth's social network is involved in, and supportive of, violence. These socioenvironmental factors are also likely to support the most extreme attitudes and behaviors related to violence that legitimize gun carrying and use. Willingness to justify shooting someone and a tendency to start fights are examples.

Our findings are not consistent with the image of otherwise law-abiding youths carrying guns solely for protection. Neither the belief that having weapons increased one's risk of being killed or injured by violence nor having been attacked or threatened with a weapon was significantly related to gun carrying after other factors in the model were controlled for. As was the case in other recent studies,[6,13,14] gun carrying could more realistically be explained as a part of an extremely aggressive, rather than defensive, system of thought and behavior.

Because respondents were not asked directly why they chose to carry a weapon, motivations for weapon carrying can only be inferred from the relationships between the hypothesized predictors and weapon carrying. The validity of self-reported motives for weapon carrying, however, is unknown and may well be poor.

Inferences based on empirical relationships between weapon carrying and suspected determinants may provide a better understanding of this key risk factor for violence.

This study is limited by its inclusion of only two junior high schools in high-crime neighborhoods in Washington, DC, and by its cross-sectional design. Additional studies are needed to determine how well these findings generalize to other youth populations. The findings also may not accurately characterize the determinants of weapon carrying among older adolescents. Although gun carrying among junior high school students appears to be primarily a function of criminal deviance and aggressive tendencies, less deviant and aggressive adolescents may later decide to start carrying guns purely for reasons of self-defense. The time sequence and causal relationships among weapon carrying and its correlates should be further delineated with longitudinal studies.

Greater insight into the determinants of weapon carrying could also come from studies that measure an array of attitudes about weapons. For example, under what circumstances do youths believe carrying a weapon is warranted? What do they think their peers think about weapon carrying, and how does this affect their decisions about whether or not to carry weapons? What fears or concerns do youths have about carrying weapons?

Provided that our findings are nominally generalizable, they may have important implications for the prevention of gun carrying among junior high school students. If gun carrying stems largely from antisocial attitudes and behaviors rather than from purely defensive motives of otherwise nonviolent youths, interventions designed to prevent delinquency may be more effective than those that focus only on educating youths about risks associated with carrying a gun. The latter may, however, be able to deter less hardened youths from carrying weapons in the future. Intensive and comprehensive interventions directed at high-risk children could possibly "inoculate" children against the many social factors that foster criminal deviance and the most violent behavior patterns.

Our study focused on individual-level determinants of weapon carrying, but the strongest determinants may be at the community or societal levels (e.g., availability of handguns, joblessness, lack of family supports, glamorization of violence). Inattention to social conditions that engender the desire, and the means, for youths to acquire guns will severely limit the effectiveness of interventions intended to change youths' attitudes and behaviors with respect to weapons. □

Young Men's Risk Behaviors for HIV Infection and Sexually Transmitted Diseases, 1988 through 1991

Leighton Ku, PhD, MPH, Freya L. Sonenstein, PhD, and Joseph H. Pleck, PhD

ABSTRACT

Objectives. This paper analyzes age- and period-related changes in risk behaviors for human immunodeficiency virus (HIV) infection and sexually transmitted diseases among young men in the United States between 1988 and 1991.

Methods. Data were from the 1988 and 1991 waves of the National Survey of Adolescent Males. The 1988 survey was a nationally representative survey of 1880 males aged 15 through 19 years. The 1991 survey was a longitudinal follow-up of 1676 males aged 17 through 22 years.

Results. As they aged, the young men increased their levels of sexual activity and decreased their condom use. Period-related changes between 1988 and 1991 were examined by comparing similar cohorts of 17.5- through 19-year-old men: there were signs that sexual activity and intravenous drug injection increased, but condom use did not change significantly. In 1991 51% of the young men said they were occasionally "high" during sex, a state that is related to reduced condom use.

Conclusions. Early progress in fostering safer behaviors among young men slowed and possibly stopped as the nation entered the 1990s. Prevention efforts need to be renewed and should focus on older youth and young adults. (*Am J Public Health.* 1993;83:1609–1615)

Introduction

The 1980s witnessed a rapid growth in public awareness about the risks of human immunodeficiency virus (HIV) and other sexually transmitted diseases. Accompanying the growth in awareness, numerous signs indicated that safer behaviors, especially behaviors relating to sexual activity and condom use, were being adopted.[1–3] Although there were initial doubts that teenagers, traditionally viewed as being resistant to prevention messages, would adopt safer behaviors, later surveys observed major changes in behaviors in response to the acquired immunodeficiency syndrome (AIDS) crisis. The level of condom use by teenaged males more than doubled between 1979 and 1988,[4] although condom use was often intermittent.[5] Teenaged females also reported substantial increases in condom use between 1982 and 1988.[6] This paper examines changes in risk behaviors for HIV infection and sexually transmitted diseases between 1988 and 1991, based on the National Survey of Adolescent Males. Behaviors examined include heterosexual and homosexual activity, condom use, and intravenous drug use.

The survey followed young men from adolescence, the period of initiation of sexual activity and other risk behaviors, into the beginnings of young adulthood, a time when sexual activity is often at its highest. The first wave of data collection occurred in 1988,[4] when publicity about AIDS may have been at its peak. The second wave of data collection occurred during late 1990 and early 1991,[7] when publicity about AIDS had decreased somewhat. For example, in June 1988, 86% of American adults recalled seeing a televised public service announcement about AIDS in the previous month[8]; this figure fell to 80% in 1991.[9] An automated search (conducted by the authors) of the *New York Times* found that the number of articles about AIDS rose between 1986 and 1988 but fell again by 1990. On the other hand, schools have offered more AIDS education in recent years, which is also salient for youth.[8–10]

Methods

The National Survey of Adolescent Males began in 1988 as a nationally representative survey of never-married, noninstitutionalized males aged 15 through 19 years living in households. The 1988 wave was conducted between April and December 1988. The original sample of 1880 males was drawn as a two-phase multistage area probability sample that oversampled Blacks and Hispanics. The original survey had a response rate of 74%. Initial sample weights were developed to account for probability of selection, nonresponse, and poststratification to match the March 1987 Current Population Survey.[11]

The second wave was conducted as a longitudinal follow-up survey about 2½ years after the initial interview, when the respondents were generally 17 through 22 years old. The follow-up survey was conducted between November 1990 and March 1991. (Hereafter, for convenience, we will simply call the second wave 1991, although about half of the data were col-

TABLE 1—Descriptive Data on Heterosexual Sexual and Contraceptive Behaviors among Young Men, 1988 and 1991

	All Respondents			Similar Cohorts[a]		
	1988 Age 15–19 y	1991 Age 17–22 y	P	1988 Age 17.5–19 y	1991 Age 17.5–19 y	P
Ever had sex with a female, %[b]	60.4	63.6	<.001	75.0	78.6	NS
Mean age at first intercourse (among those sexually experienced), y[c]	14.9	15.6	<.001	15.4	15.2	<.05
Contraceptive use at last intercourse[b]						
Condom, %	56.2	44.2	<.001	53.0	55.9	NS
Female contraceptive method (without condom), %[d]	20.6	33.0		26.9	22.8	
No or other method, %	23.1	22.9		20.1	21.3	

Note. Ages are given in conventional chronological years (e.g., 15–19 includes up to 20th birthday). NS = not significant.
[a]In both periods, cohorts were never-married, noninstitutionalized 17.5- through 19-year-olds.
[b]Tested by chi-square.
[c]Tested by *t* tests.
[d]Female contraceptive methods include oral contraceptives, diaphragm, intrauterine device, contraceptive foam or jelly, and Today sponge. When combined with condom use, these methods are classified under condom use.

lected in late 1990.) Using a variety of tracking methods, we were fortunate to have an 89% follow-up rate and to retain 1676 respondents in the sample. (This number does not include 11 respondents who died between the two interview periods. Consistent with the national profile for young men's mortality, 4 died as a result of motor vehicle accidents, 4 were victims of homicide, and 3 committed suicide. One is reported to have committed suicide because he was HIV-positive.) Nonresponse analysis indicates that those who were lost to follow-up tended to be slightly older, although there were no significant differences by racial/ethnic group. More important, there was no significant attrition bias in any of the behavioral outcomes of interest). Longitudinal sample weights were developed that were based on the original weights, adjusted for loss to follow-up. In general, all analyses presented in this paper are weighted.

In both waves of the survey, the primary mode of data collection was face-to-face interviews, conducted in a confidential setting, between trained interviewers and the respondents. The most sensitive topics (e.g., substance use, risky sexual behaviors) were assessed with confidential self-administered questionnaires that the interviewer did not see. Recent methodological research compared self-administered questionnaires about drug use with face-to-face interviews and found that people were more likely to report sensitive behaviors in self-administered questionnaires.[12] In the follow-up, 32 interviews were conducted by telephone because it was not possible to conduct a personal interview. Some of those interviewed by telephone were in the military and had been mobilized for Operation Desert Shield/Desert Storm. It is important to remember that all data presented here are self-reported data of a sensitive nature and may be subject to intentional and unintentional reporting errors.

The number of acts of intercourse and consistency of condom use in the previous 12 months were constructed variables, based on partner-by-partner data for up to six partners in the previous year for 1988 and up to eight partners in the previous year for 1991. For relationships initiated earlier than 12 months before the interview, the proportion of acts of intercourse falling within the previous year was estimated based on the proportion of the relationship that had occurred within the 12-month window. For respondents with more than six partners in 1988 and those with more than eight partners in 1991, the number of acts of intercourse with the additional partners was imputed based on the levels for the partners with data available.

Results

Changes in Heterosexual Behaviors between 1988 and 1991

Public health efforts to stem HIV and other sexually transmitted infections focus on reducing levels of sexual activity (e.g., delaying initiation of sexual activity or reducing the number of partners) and increasing the use of condoms to protect against disease transmission. Previous analyses of the 1988 survey data found changes in sexual behavior and condom use compared with Zelnik and Kantner's 1979 National Survey of Young Men. For 17- through 19-year-old metropolitan males, the rate of condom use at last intercourse rose from 21% in 1979 to 58% in 1988. At the same time, however, there was a modest increase in the proportion of 17- through 19-year-olds who had had sexual intercourse: 66% were nonvirgins in 1979, vs 76% in 1988.[4] However, among sexually active teens, there were modest reductions in the number of partners and in the frequency of intercourse in the previous 4 weeks between 1979 and 1988.[13]

Table 1 compares a variety of standard measures of heterosexual activity and condom use between 1988 and 1991. In this table and in Tables 2 through 4, the columns headed "All Respondents" contrast the complete samples in 1988 and 1991. In a conventional longitudinal fashion, they indicate the status of the young men as they aged over the 2½ years of follow-up. The columns headed "Similar Cohorts" present data for subsamples who were similarly defined for each period: never-married, noninstitutionalized young men who were 17.5 through 19 years old. This strategy essentially examines the older half of the sample in 1988 and the younger half in 1991. The similar cohorts are almost completely independent. Only 12 of the sexually active men (1%) appear in both samples, owing to slight slippage in the 2½-year interval between interviews.

The proportion of all respondents who had had intercourse rose from about three fifths in 1988 (when they were 15 through 19 years old) to about five sixths in 1991 (when they were 17 through 22 years old). The proportion using condoms at last intercourse fell by about 12 percentage points, from 56% in 1988 to 44% in 1991. However, this decrease was offset by a switch to female contraceptive methods. Although there was an age-related decrease in use of condoms to protect against HIV or other sexually transmitted diseases, there was no net decline in protection against pregnancy.

Were these changes due to the fact that the respondents were 2½ years older at the time of the second interview, or to the fact that one survey was done in 1988 and the next in 1991? There were no significant changes in the proportion of re-

spondents in the similar cohorts (17.5- through 19-year-olds) who had ever had sex, nor were there any significant changes in condom use. The shifts in sexual experience and contraceptive use seen in the overall sample appear to be primarily attributable to the fact that the respondents were 2½ years older in 1991.

Although the overall proportion of 17.5- through 19-year-olds who were sexually experienced did not change between 1988 and 1991, there was a small but significant decline in mean age at first intercourse, from 15.4 to 15.2 years ($P < .05$). There were other indications of changes in sexual activity, shown in Table 2. For both all respondents and the similar cohorts, there were significant increases in the mean number of partners in the previous 12 months and in the mean number of acts of intercourse in the previous 12 months and in the previous 4 weeks. The proportion of young men with five or more partners in the previous year also increased. Generally, sexually active young men reported beginning their sexual careers a little earlier, having more partners, and having somewhat more frequent intercourse in 1991 than in 1988. In both Tables 1 and 2, there is a small, nonsignificant trend toward increased condom use among the 17.5- through 19-year-olds. Regardless of statistical significance, the magnitudes of the differences are quite small.

Table 3 presents selected statistics by racial/ethnic group. Because samples sizes are smaller within racial groups, statistical power is reduced. For the overall sample, there were increases in the mean number of partners in the previous 12 months for all races, although the difference was not significant for White youths. That is, most young men tended to have more partners in a year as they aged into their late teens and early 20s. For the 17.5- through 19-year-olds, there were significant increases in the number of partners for Black youths, although the trends increased for White and Hispanic youths also. In the overall sample, the consistency of condom use fell by a mean of 8 to 10 percentage points for all racial/ethnic groups as they aged 2½ years. Condom use was more common among Black men in both 1988 and 1991.

TABLE 2—Heterosexual Sexual Activity and Condom Use among Young Men, 1988 and 1991

	All Respondents			Similar Cohorts[a]		
	1988 Age 15–19 y	1991 Age 17–22 y	*P*	1988 Age 17.5–19 y	1991 Age 17.5–19 y	*P*

Changes in Higher-Risk Behaviors: Drug Injection and Homosexual Intercourse

The epidemiology of HIV and sexually transmitted disease infection indicates that certain behaviors are associated with a heightened risk of becoming infected or infecting one's partner.[2] These behaviors include using intravenous drugs, being the partner of an intravenous drug user, being the partner of a prostitute, and having homosexual intercourse, especially receptive anogenital intercourse. To maximize responses, all questions about these behaviors were asked by self-administered

TABLE 4—Frequencies of Behaviors Associated with Higher Risk of HIV and Sexually Transmitted Disease Transmission among Young Men, 1988 and 1991

	All Respondents, %			Similar Cohorts, %[a]		
	1988 Age 15–19 y	1991 Age 17–22 y	P^b	1988 Age 17.5–19 y	1991 Age 17.5–19 y	P^b
Ever had sex with a prostitute	0.7	2.5	<.001	1.0	1.6	NS
Ever had sex with an intravenous drug user	0.7	1.2	NS	1.4	0.9	NS
Ever used intravenous drugs	0.5	1.6	<.01	0.5	2.1	<.01

Ever had oral or anal intercourse with another male	1.5	1.0	NS	1.9	0.7	<.05
Ever had receptive anogenital intercourse with another male	0.9	0.5	NS	1.9	0.2	<.05

Note. In this table, the percentages use all respondents as the denominators. Ages are given in conventional chronological years (e.g., 15–19 includes up to 20th birthday). NS = not significant.
[a]In both periods, cohorts were never-married, noninstitutionalized 17.5- through 19-year-olds.
[b]Tested by chi-square.

questionnaires, but even so, most researchers would agree that these very sensitive items are probably underreported. As seen in Table 4, each of these behaviors was reported by fewer than 3% of the respondents in our sample. The very small sample sizes severely limit statistical power and indicate the problems in trying to survey relatively rare or stigmatized behaviors. With regard to these behaviors, researchers are concerned that bias may arise because disproportionate numbers of people at high risk may fail to participate in the survey or to answer specific questions.

For all respondents, there was a significant increase in the proportion of respondents who reported having sex with a prostitute or paying someone for sex, but this increase appears to be age-related because the 17.5- through 19-year-old groups were not significantly different. There were also significant increases in the percentage of respondents who reported using intravenous drugs, both for all respondents and for the 17.5- through 19-year-old similar cohorts. For the 17.5- through 19-year-olds, the percentage reporting intravenous drug use rose from 0.5% in 1988 to 2.1% in 1991. For both sex with prostitutes and intravenous drug use, the apparent increases might have been at least partly caused by small changes in question wording between 1988 and 1991. (The self-administered questionnaire asked in 1988, "Have you ever had sex with a prostitute?" In 1991, "Have you ever had sex with a prostitute or with someone you paid for sex?" In 1988, "Have you ever taken street drugs using a needle?" In 1991, "Have you ever taken street drugs, like heroin or cocaine, using a needle? This includes 'shooting up' and 'skin popping.'")

One of the most sensitive risk behaviors is homosexual activity. The percentage of young men who said they had ever engaged in sex with another man fell between 1988 and 1991, but we warn that the responses given were not reliable. For example, 30 respondents (unweighted) reported ever having oral or anal intercourse with another male in 1988, but in 1991 only 11 of these respondents acknowledged ever having oral or anal intercourse. Thirteen respondents who reported no oral or anal intercourse in 1988 said that they had engaged in these behaviors by 1991, although this change may reflect real changes in status. We checked and ruled out the possibility that this change was due to attrition of men with homosexual activity in 1991. It is plausible that some respondents were more open about their experiences in 1988 than they were 2½ years later. Although most survey researchers are aware of the difficulty of eliciting responses about extremely sensitive, stigmatized topics, this finding also raises questions about time-related reporting bias in retrospective data. These inconsistent findings prohibit us from drawing any firm conclusions about actual changes in the level of homosexual activity for young men between 1988 and 1991.

Risky Heterosexual Behaviors in 1991

In 1991 the survey included questions about drug and alcohol use related to sexual activity and about heterosexual anal intercourse. In addition to general public health concerns about substance use, there are specific concerns that if one or both members of a couple are high on drugs or alcohol during sex, they may be less responsible and less likely to use condoms or other contraception.[14] In earlier analyses of 1988 data, higher levels of cocaine or alcohol use were generally correlated with other risk behaviors, including having more partners, having intercourse more often, and using condoms less often.[5] The concern about anal intercourse is twofold. First, people may be less likely to use condoms during anal intercourse because the woman cannot get pregnant. Second, there may be a higher risk of transmission of HIV or other sexually transmitted diseases during unprotected anal intercourse because there may be greater physical trauma than during vaginal intercourse.

More than one quarter (26.3%) of sexually active young men said that they had been drinking before last having intercourse; 3.5% said that they had used drugs and 2.3% had used both drugs and alcohol. (The interviewer asked, "Before you had sexual intercourse the last time, had you been drinking wine, beer, or other alcoholic drinks?" "Before you had sexual intercourse the last time, had you been using marijuana, cocaine, or other drugs?") Asked about the extent to which they had been high on alcohol or drugs when having intercourse during the previous year, about half (49.3%) said that they never had been high and about 13% said that they had been high about half the time or more often. (The self-administered questionnaire asked, "During the last 12 months, how often were you 'high' on alcohol or drugs when you had sexual intercourse with a female?")

Black men reported using alcohol or drugs before sex less often than did White or other-race men. The comparisons between Black and Hispanic men are a little inconsistent: Black men reported using substances at last intercourse less often than did Hispanic men, but the distributions for being high over the previous year were quite similar for Black and Hispanic men. Substance use during sex generally increased with older ages.

As seen in Tables 5 and 6, substance use preceding sex was associated with reductions in condom use, both at last intercourse and over the previous 12 months. Measured over a 12-month period, substance use preceding sex was also associated with a larger number of part-

ners and a greater frequency of intercourse. The relationships are not linear—that is, more substance use is not consistently related to more sexual activity—but the general trend is positive. This indicates that substance use poses double health threats. First, those who drink or use drugs prior to sex tend to have a greater volume of sexual activity, elevating the number of exposures to potential disease transmission. Second, the substance users are less likely to use condoms or female contraceptives, increasing the risk of any given act of intercourse.

About 9% of sexually active young males reported engaging in heterosexual anal intercourse in the previous 12 months (1 or 2 times, 4.0%; 3 to 10 times, 4.1%; more than 10 times, 0.8%). Unfortunately, 60% of those who engaged in anal intercourse never used condoms during anal intercourse and only 20% always used them. These rates of condom use are much lower than rates for vaginal intercourse. Although young people are aware of the need for protection during vaginal intercourse, they are probably less aware of its relevance during a riskier type of intercourse.

Discussion

Heterosexual Behaviors and Condom Use

As teenaged males move toward young adulthood their level of sexual activity increases (proportion nonvirgin, mean number of partners per year, mean frequency of intercourse) and condom use decreases. This pattern has been observed cross-sectionally[4,5,15] and is demonstrated longitudinally here. As males age, they tend to switch from reliance on condoms toward use of female contraceptive methods, especially oral contraceptives. Because they are more sexually active, the risk of HIV or sexually transmitted disease transmission becomes that much greater.

When we controlled for age differences through selection of similar cohorts, there were no significant changes in condom use or in the proportion of those sexually experienced between 1988 and 1991, but there were signs that 17.5- through 19-year-olds, particularly Black and other-race males, had more partners and more frequent intercourse in 1991 than in 1988. Why did the reported levels of sexual activity rise? Both methodological and substantive explanations are possible. On the methodological side, although we have defined the 17.5- through 19-year-olds to be as similar as possible, a key difference is that in 1991 the respondents were participating in the survey for a second time. The respondents may have been "conditioned" by having been interviewed in 1988. Respondents may have been more restrained in their responses to the first survey and less restrained in the second survey, leading to higher reports of sexual activity in the second survey. This could mean that reports in 1988 were understated or that reports in 1991 were overstated. We examined and ruled out the possibility that these findings were caused by attrition bias among those lost to follow-up; there were no significant differences in 1988 behaviors among those were followed up and those who were not.

The most likely explanation is that period-related increases in sexual activity did occur. This possibility is corroborated by the fact that the national rate of births to teenaged females rose between 1988 and 1990.[16] In contrast to our findings, the Centers for Disease Control's (CDC's) Youth Risk Behavior Survey, a nationally representative survey of high school students, found modest reductions in the proportion of students who had ever had intercourse and also found a reduced number of lifetime partners between 1989 and 1991.[10] The discrepancies may be due to the fact that the CDC high school sample was younger than our sample, to the fact that it pooled male and female students, or to the fact that it used a slightly different time frame.

Although there were large increases in condom use by adolescent males between 1979 and 1988,[4] there were essentially no increases between 1988 and 1991. The CDC also failed to find significant overall changes in the rate of condom use at last intercourse between 1990 and 1991.[10] There are also some signs that the sales of condoms slowed: market research data indicated that condom sales fell between 1990 and 1991[17]; other data showed declines in sales between 1991 and 1992.[18]

Higher-Risk Behaviors

The reported levels of intravenous drug use by males aged 17.5 through 19 years rose between 1988 and 1991. Changes in question wording make interpretation difficult. The National Household Survey on Drug Abuse indicates that drug injection among adolescents (aged 12 through 17 years) rose from 0.4% in 1988 to 1.6% in 1990, although there were no significant changes among people aged 18 through 25 years.[19,20] The CDC survey of high school students found no changes in level of reported drug injection between

1990 (1.5%) and 1991 (1.6%).[10] Although the percentage of adolescents using intravenous drugs is small, any apparent increase in drug injection is a cause for concern. Intravenous drug users are at greater risk not only for HIV infection but also for other serious health and social problems.

Our findings about homosexual behavior should not be interpreted as indicating a decline in the prevalence of homosexual activity. As discussed above, young men provided inconsistent responses to these questions. Although researchers can and should be willing to ask about sensitive behaviors, some methodological problems remain. The apparent reversal in responses among respondents who acknowledged homosexual intercourse in the first interview is troubling. Although we made strong efforts to be sensitive and to safeguard respondents' confidentiality, there was evidence that males were very reluctant to report engaging in sex with another man. Perhaps other methods, such as randomized response or item count techniques, are better suited to obtaining this information; however, it may be that men suppress this information so strongly that no interview process will obtain valid results. Further methodological research may help inform survey researchers about the best ways to study these important but highly stigmatized behaviors. The controversy about a recent report on adult male sexual behavior[21] indicates the level of interest in and methodological concerns about the measurement of these risk behaviors.

Conclusions

We examined a wide range of risk behaviors for HIV infection and sexually transmitted diseases among a nationally representative sample of young men in the United States from 1988 to 1991. Insofar as these behaviors are self-reported sensitive behaviors, there is potential for intentional and unintentional misreporting that may bias findings. On the other hand, many survey researchers believe that trend data are more reliable indicators, because biases present in one time period probably affect the other time period as well. Thus, even if an estimate for one time period is biased, trends between two time periods may be valid.

A great deal of policy and research attention has focused on teenagers. This study suggests that the transition from adolescence to adulthood is a period of even greater risk. As young men age, they tend to have more sexual activity, to use condoms less, and to engage in riskier sex (sex with prostitutes and substance use before sex). There has been a gratifying and potentially important increase in the prevalence of school-based AIDS education. From a public health perspective, we need to develop better means to reduce risk among older youths and young adults who are no longer in school, whether because they have dropped out or because of graduation. It is important to develop programs that can continue to provide educational messages and reinforcement in the community.

Previous studies have indicated that young Americans modified their behaviors during the late 1980s to reduce their risks of HIV or sexually transmitted disease transmission, including increasing condom use,[4] reducing the number of partners,[13] and reducing intravenous drug use.[22] The data reported here indicate that the trend toward safer behaviors has, at the very least, slowed. Indeed, there is evidence that the movement has stopped or even reversed. When similar cohorts of males aged 17.5 through 19 years were compared, there were signs that sexual activity (number of partners and frequency of intercourse) had increased between 1988 and 1991 and there were no significant increases in condom use. Although there were nonsignificant increases in condom use, they certainly do not compare in magnitude to the large increases witnessed earlier in the decade. It is of serious public health concern that there were signs, albeit imperfect, that intravenous drug injection rose among teenagers. Although intravenous drug use affects a very small proportion of youth, it is an extremely serious risk factor for HIV, as well as being a serious problem unto itself.

Why has the progress in behavioral change slowed and possibly even reversed? We posit two possible reasons. First, AIDS is no longer a new disease and therefore it has begun to shift in people's perception from being a dread disease toward being more commonplace.[23] Second, publicity about AIDS appears to have fallen off in the past few years. Although general publicity about AIDS has been declining, it appears that school-based AIDS education continues to grow.[10] Regardless of the cause, public health officials are faced with the challenge of renewing public interest in safer behaviors associated with AIDS and sexually transmitted diseases. Such an effort would not be futile, especially if it were directed at the youth who are most at risk. There was strong evidence that teenagers developed safer behaviors during the 1980s. Other research has indicated that AIDS education and sex education are associated with safer behaviors.[24,25] Over the years, public health policy has developed many tools to foster more responsible behaviors, but the effort needs reinvigoration. Although prevention messages should be directed at all groups, there is a special need to reach older youth and young adults. □

Acknowledgments

Both waves of the National Survey of Adolescent Males were supported by grants from the National Institute for Child Health and Human Development.

Portions of this paper were presented at the annual meeting of the Population Association of America, Denver, Colo, May 1992.

Data collection was conducted by the Institute for Survey Research, Temple University, under the skillful direction of Koray Tanfer, Lisa Cope, and Christine Schuler. We gratefully acknowledge the research assistance of James Kershaw.

National Environmental Tobacco Smoke Conference to Be Held in December

The National Environmental Tobacco Smoke Conference, "Programs, Policy, Litigation and Liability," will be held December 16 and 17, 1993, at the Hyatt Regency on Capitol Hill, Washington, DC. Sponsored by IAQ Publications, the conference will cover the entire spectrum of secondhand smoke issues, including federal, state, and local policies and programs; options for in-place management of environmental tobacco smoke; litigation and liability; smokers' rights; tenant and employee rights; model programs and environmental tobacco smoke legislation; response to environmental tobacco smoke issues from the restaurant, hospitality, and tobacco industries; and the agendas of public interest and consumer groups.

Technical and general sessions will feature special appearances by US Environmental Protection Agency, Occupational Safety and Health Administration, National Institute for Occupational Safety and Health, and Centers for Disease Control and Prevention officials, along with building managers, attorneys, evaluation and mitigation authorities, public health officials, and representatives from the US House and Senate.

Those who should attend include environmental lawyers, federal and state government policymakers and officials, public health officials, building owners and managers, hospitality and restaurant industry executives, industrial hygienists, occupational health and safety personnel, environmental health professionals and consultants, and insurance executives and underwriters.

For more information, contact IAQ Publications, 4520 East-West Hwy, Suite 610, Bethesda, MD 20814; tel (301) 913-0115; fax (301) 913-0119.

Anthropometry and Childhood Mortality in Northwest and Southwest Uganda

Venanzio Vella, PhD, Andrew Tomkins, MD, Armando Borghesi, MD, Giovanni Battista Migliori, MD, John Ndiku, MD, and Basil Charles Adriko, MD

ABSTRACT

Two longitudinal studies were carried out in northwest and southwest Uganda to examine the relationship between anthropometry and childhood mortality. Although the prevalence of malnutrition was significantly different between the two geographic areas, the relative risk for mortality associated with low levels of anthropometry was similar. When the anthropometric parameters were compared among each other, mid-upper arm circumference was found to be the most powerful predictor of mortality. The findings of this study confirm that mid-upper arm circumference is the indicator of choice to identify children at higher risk of death. (*Am J Public Health.* 1993; 83:1616–1618)

Introduction

The strength of the relationship between malnutrition and mortality differs according to the country, the type of anthropometric parameter used, and the cut-off point selected.

Sommers and Lowenstein[1] showed a relative risk of 3.4 for children below the 10th percentile of arm circumference for height compared with those above the 50th percentile. Kielmann and McCord[2] found that among Indian children, mortality decreased exponentially with each 10% rise in median weight for age. In a study carried out in Bangladesh, Chen et al.[3] found a relative risk of around 3 among children who were below 60% in weight for age, with mid-upper arm circumference and weight for age being the most sensitive predictors of mortality. Briend et al.[4] confirmed in Bangladesh that mid-upper arm circumference had the highest sensitivity compared with weight for age, weight for height, and height for age.

However, other studies conducted in Guinea Bissau[5] and Zaire[6] showed a poor predictive power of anthropometry. Therefore, mortality associated with anthropometry varies between countries, and what has been found in Asia may not be applicable to Africa. This could be owing, in part, to the lower prevalence of wasting in Africa associated with a lower variability within the socioeconomic structure.[7]

This study sought to determine whether anthropometry can be used in an African country to identify children at higher risk of death.

Methods

In 1987 and 1988, 5498 children under 5 years of age were selected from 61 villages in two districts in northwest and southwest Uganda. The villages were selected with cluster sampling, with probability proportional to size. All the children residing in the villages were measured for weight, height (for children above 2 years of age), and length (for children below 2 years of age), and, in the southwest villages, for mid-upper arm circumference as well. A salter spring scale was used to measure weight within the nearest 100 g, and locally constructed boards were used to measure length and height to the nearest millimeter. Measurement techniques conformed to the United Nations manual, *How to Weigh and Measure Children.*[8]

Follow-up visits to all families 12 months later were used to assess mortality of the study children. The data were entered, cleaned, and analyzed using the Statistical Package for the Social Sciences (SPSS).[9] We transformed measurements into standard deviation scores of the median reference of the National Center for Health Statistics[10] using the Centers for Disease Control and Prevention package.[11]

The views expressed in this article are the authors' and do not necessarily reflect those of the Uganda Ministry of Health, UNICEF, or CUAMM.

Results

Malnutrition was significantly higher in the northwest than in the southwest, but the mortality rates associated with low levels of anthropometry were similar in the two areas (Tables 1 and 2).

When levels of anthropometric parameters were compared, mid-upper arm circumference was associated with a relative risk for mortality that was significantly higher than that associated with other parameters (Tables 3 and 4). The relative risk for mortality associated with less than 11.5 cm of mid-upper arm circumference was more than 2 when compared with a standard deviation of less than −3 for weight for age, and less than −2 for weight for height and it was more than 4 when compared with a standard deviation of less than −3 for height for age. Low levels of weight for age and weight for height had almost the same relative risk, which was higher than that associated with low levels of height for age.

TABLE 1—Prevalence of Childhood Malnutrition and Mortality below Defined Anthropometric Cutoff Points, Northwest (NW) and Southwest (SW) Uganda

Cutoff	Geographic Area	Prevalence n	Prevalence %	Mortality below Cutoff n	Mortality below Cutoff %	Sensitivity	Specificity
<−3 SD W/A	NW	75/1066	7.0*	8/75	10.7	23	93
	SW	132/3768	3.5	12/132	9.1	12	97

Discussion

Previous studies found that mid-upper arm circumference and weight for age were the most sensitive predictors of mortality in Asia[2-4]; however, these results were not confirmed in Guinea Bissau[5] and Zaire.[6] This suggests that anthropometry might play a relatively minor role in Africa in identifying children at higher risk of death. The data from this study confirm that, in Uganda, low levels of anthropometry are significantly related to mortality, with mid-upper arm circumference being the best predictor of mortality.

Although it is not possible to generalize the results outside the two areas surveyed, we can expect the results to be valid for this part of Africa. From a previous analysis not presented in this paper, the predictive power of mid-upper arm circumference for mortality was independent of age and was not improved by the addition of the other anthropometric parameters.[12] Besides being the most powerful predictor of mortality, mid-upper arm circumference does not need the knowledge of age below 5 years; it is cheap, quick, and easy to use; and it has fewer sources of error than other parameters. With a simple color-coded tape, mid-upper arm circumference could be used by those who are illiterate, with the advantage of identifying children at risk more effectively than other measuring methods.

Beyond these advantages, the effectiveness of mid-upper arm circumference is supported by the fact that, in the southwest, 45% of mortality was concentrated below 13.5 cm of mid-upper arm circumference. Considering that 17% of the examined children were below this measure and that 95% of the deaths below this cutoff point were due to infectious diseases, a reduction in mortality of 43% (95% of 45%) is theoretically possible if resources were prioritized on the 17% of the child population identified by mid-upper arm circumference as being at risk. In conclusion, this study confirms that the best indicator to identify children at risk is mid-upper arm circumference, which could be considered a simple and comprehensive proxy of deprivation to be used for target-

The Authorship and Fate of International Health Papers Submitted to the *American Journal of Public Health* in 1989

Dieter Koch-Weser, MD, PhD, and Alfred Yankauer, MD, MPH

ABSTRACT

We reviewed the authorship characteristics, editorial processing, and final fate of 126 papers dealing with data from countries other than the United States and Canada and submitted to the *American Journal of Public Health* in 1989. The acceptance rate of these international health papers was 22%, similar to that of all papers (25%). Authors from developed countries had higher acceptance rates than authors from developing countries, but the highest acceptance rate (36%) was for international health papers with joint authorship from both developed and developing countries. Of 83 rejected papers, 72% were published in other journals. Of these, 45% were published in journals covered by *Index Medicus*, a figure similar to that for all papers rejected by the Journal. (*Am J Public Health.* 1993;83:1618–1620)

Introduction

The *American Journal of Public Health*, the official journal of the American Public Health Association, is widely read throughout the world. Therefore it is understandable that health professionals from other countries submit papers to the Journal in the hope of reaching its broad readership.

In recent years, however, the Journal has noted an increase in the number and proportion of papers received from countries other than the United States and Canada, as well as an increase in the acceptance rate of such papers (Table 1). Stossel and Stossel observed a similar phenomenon in papers published by four prestigious English language journals from 1977 to 1988.[1] We decided to explore this situation in greater depth by describing the authorship, processing, evaluation, and eventual outcome of all international papers received by the Journal in 1989.

Methods

In Table 1, only papers received from countries outside the United States and Canada are defined as international health papers. We have also examined accept-

[a]Papers dealt with data from other countries.

ance rates when international health papers are defined as papers from investigators based in US and Canadian institutions whose research dealt with data from other countries. We recorded authors' names, institutional affiliations, and data sources; the comments of reviewers and the Editor; and the Editor's decision; if rejected, we recorded the reason for rejection.

Eighteen to 30 months later, a letter from the Chair of the International Health Section of the American Public Health Association queried the first authors of all rejected papers by mail to determine whether their papers had been sent to another journal before being submitted to the *American Journal of Public Health,* whether the papers were sent to another journal after rejection, and the outcome of the latter submission. Nonrespondents were contacted by telephone.

Results

Of the 1043 manuscripts submitted to the Journal in 1989, complete information was available on 1013, 126 of which were international health papers as defined by us. The acceptance rate of these 126 papers was 22%, essentially the same as that of papers dealing with data from the United States or Canada (25%). Thirty-one of the international papers were rejected by the Editor without external review. A similar proportion of all papers received by the Journal in 1989 were rejected without external review (A.Y.).

The first author of all international health papers was more often the citizen of a developed country, and the acceptance rate of such papers was substantially higher than that of papers whose first author came from a developing country (Table 2). Sixteen papers, all of whose authors were American or Canadian, had acceptance rates of 25%, compared with an acceptance rate of 17% for 82 papers authored by only foreign authors. However, the 28 papers with authors from both foreign and US/Canadian institutions fared best of all with an acceptance rate of 36%.

The Editor followed the advice of both reviewers for 25 of the 28 accepted papers; for 3 accepted papers he agreed with one reviewer, whereas the other reviewer recommended rejection. For 62 rejected papers that were reviewed externally, the editor agreed with both reviewers in 32 cases, the reviewers disagreed between themselves in 20 cases, and in 10 cases both reviewers recommended acceptance of papers that the Editor rejected. These proportions are similar to those found in an in-house study by one of us (A.Y.). The authors of four papers were asked to revise but failed to respond to repeated queries. One paper turned out to have been published previously and was therefore rejected.

The reasons for rejection of 93 papers were as follows: 16 provided no new information, 40 were technically flawed, 21 were deemed to be of only local interest, and 16 were considered more appropriate for clinical or specialty journals.

Eighty-three of the first authors of the 98 rejected papers answered the follow-up query. Twelve had tried to publish their papers in journals listed in the *Index Medicus* prior to submission to the Journal. After rejection by the Journal, 63 (76%) resubmitted their paper to other journals and 60 (72%) were accepted, 37 (45%) by a journal covered by *Index Medicus.*

Discussion

Although many international health papers require more than the usual editorial attention, there was no bias against them in the editorial process. Their acceptance rate was similar to that of all papers. The proportion rejected without review and the proportion rejected against the advice of one or more reviewers were also similar to those of all papers. The high acceptance rate of rejected papers by other journals is only slightly less than that reported for the *Journal of Clinical Investigation*[2] and the *New England Journal of Medicine* in 1978.[3] The proportion published in journals covered by *Index Medicus* is similar to that of all papers rejected by the *American Journal of Public Health.*[4]

The fact that only a fifth of the first authors of international health papers were from developing countries can be explained by the dearth of research in these countries.[5] Many health professionals from developing countries who are well trained in Europe, Canada, or the United States have difficulty finding suitable jobs in their countries of origin.[6] In some instances they have even encountered hostility and opposition by rigid local hierarchies when they return.[7] The acceptance rate of papers all of whose authors were from developing countries was low. Many such papers dealt with routine local service statistics or failed to contribute to the field of international health.

On the other hand, epidemiologic and health service research from developing countries is often relevant to North American professionals. A new journal of international public health has been suggested to accommodate such papers. However, we believe establishment of such a journal could deprive *American Journal of Public*

Health readers of information relevant to their own interests and that the concept of thematic issues of the Journal is a better way of increasing the number and improving the quality of international health papers.

Several successful programs are trying to promote the development of health service and epidemiologic research in the developing world. Among them are the Independent International Commission on Health Research for Development,[8] the International Clinical Epidemiology Network,[9] the Rockefeller Foundation's Greatly Neglected Diseases Network,[10] and several World Health Organization initiatives, such as the Tropical Diseases Research Program. All of these programs aim at international cooperation in research. The fruits of such international collaboration are reflected in the Journal's high acceptance rate of papers whose authors were from both developing and industrialized countries. □

Acknowledgments

Screening for Colorectal Neoplasia: Physicians' Adherence to Complete Diagnostic Evaluation

Ronald E. Myers, PhD, DSW, Andrew M. Balshem, BA, Thomas A. Wolf, MA, Eric A. Ross, ScM, and Lois Millner, PhD

ABSTRACT

This prospective study was done in a health maintenance organization colorectal cancer screening program to determine whether 166 persons found to have abnormal fecal occult blood test results typically underwent complete diagnostic evaluation (i.e., either colonoscopy or barium enema x-ray plus flexible sigmoidoscopy). Chart audit data show that 137 (82%) subjects contacted a physician to discuss follow-up. A complete diagnostic evaluation was recommended to only 52 (38%) patients who talked with a physician. Forty-two (81%) patients who were advised to get a complete diagnostic evaluation actually complied. Significant differences in clinical findings were observed for patients who did and did not have a complete diagnostic evaluation. (*Am J Public Health.* 1993;83:1620–1622)

Introduction

During their lifetimes, American men and women have about a 5% chance of developing large-bowel cancer.[1,2] Recent figures indicate that in 1992, there were over 156 000 new colorectal cancer cases and more than 58 300 deaths from colorectal cancer.[3]

Screening programs for colorectal cancer usually employ fecal occult blood tests to detect early-stage cancer. This screening test is recommended by the American Cancer Society and the National Cancer Institute for annual use by men and women 50 or more years of age. Controlled trials are being carried out in the United States and Europe to determine whether mortality can be reduced by screening for fecal occult blood.[4–8]

It is recommended that persons with abnormal fecal occult blood test results undergo complete diagnostic evaluation (i.e., either colonoscopy or barium enema x-ray plus flexible sigmoidoscopy).[9,10] The study described here is a prospective assessment of adherence to complete diagnostic evaluation guidelines in colorectal cancer screening.

Methods

In spring 1989, a cohort of men and women (n = 2201) 50 or more years of age was randomly selected from 12 800 individuals who had joined HMO PA/NJ within the previous year. HMO PA/NJ is a prepaid health care plan of US Healthcare Inc, an independent practice association-type health maintenance organization (HMO). On joining the HMO, each subject had selected an affiliated primary-physician office as his or her medical care provider. Study subjects were mailed a

free screening kit, which included three HemaWipe fecal occult blood tests, through an HMO colorectal cancer prevention program known as US HEALTHCARE CHECK. Persons who did not return tests within 15 days were mailed a reminder letter. Subjects whose test results were positive (n = 166) were notified by mail, as were the offices of their primary physician (n = 121). The subject notification letter encouraged recipients to discuss follow-up with their primary physician. A medical chart audit was done 6 months later to collect data on diagnostic evaluation and diagnosis.

Results

The chart audit revealed that 137 (83%) subjects had contacted a primary physician to discuss follow-up. This figure was significantly lower (P = .0006) than our projected rate of contact (i.e., 90%).[11] For 18 (11%) subjects, there was no record in the chart of any contact in which follow-up of the abnormal test result was discussed. In 11 (7%) cases, no patient chart could be located. This situation indicates that the patient had never visited the office.

For the 137 patients who had contacted a physician, it was found that only 52 (38%) were advised to have a complete diagnostic evaluation; 75 (55%) were advised to have diagnostic procedure(s) other than a complete evaluation. Recommended procedures other than a complete diagnostic evaluation included a repeat fecal occult blood test (n = 34), digital rectal examination (n = 18), barium enema x-ray (n = 14), complete blood count (n = 14), flexible sigmoidoscopy (n = 8), upper gastrointestinal x-ray (n = 7), rigid sigmoidoscopy (n = 3), and other unspecified procedures (n = 2). The number of procedures totals more than 75 because some patients were advised to have more than one procedure. Finally, it was determined that 10 (7%) patients were advised to have no further workup. It was also discovered that of the 52 individuals who were advised to have a complete diagnostic evaluation, 42 (81%) actually underwent the procedure(s).

Differences in findings for subjects who did and did not undergo complete evaluation were marked (P < .0001).[12] Specifically, diagnoses of patients for whom it was verified that a complete diagnostic evaluation was done (n = 42) included 1 cancer case, 10 polyp cases, 21 "other" cases (i.e., hemorrhoids, diverticulitis, stomach ulcer), and 10 cases with normal findings. Diagnoses recorded for patients who underwent procedures other than complete evaluation (n = 75) were 3 polyp cases, 25 "other" cases (i.e., hemorrhoids, diverticulitis, stomach ulcer), and 57 cases with normal findings. No diagnosis was available for 20 subjects.

Discussion

Complete diagnostic evaluation is routinely done for persons with a positive fecal occult blood test result in randomized controlled trials. When colorectal cancer screening is done at the community level, however, complete evaluation of abnormal test results is often not done.[13–15] We have discovered that most patients with an abnormal fecal occult blood test contact a physician to discuss follow-up care; however, many do not actually undergo a complete diagnostic evaluation. Our findings are consistent with a recent report that suggested that 37% to 63% of patients who present at a physician's office with an abnormal fecal occult blood test result undergo a complete diagnostic evaluation.[16] For individual patients, incomplete diagnostic evaluation may result in delay or failure to detect colorectal cancer and polyps. At the population level, a low rate of complete diagnostic evaluation in a screening program is likely to minimize any potential contribution of screening to the reduction of morbidity and mortality. It should be noted that the problem of incomplete diagnostic evaluation has also been reported in screening for other types of cancer.[17–19]

By observing physician–patient contact in follow-up care, we also found that most persons with a positive fecal occult blood test result had consulted with a physician; however, in most cases, it appears that they were not advised to have a complete diagnostic evaluation. The practice of recommending follow-up procedures other than complete diagnostic evaluation may reflect physicians' uncertainty about preventive care in general[20–22] or about colorectal cancer screening in particular.[23] It may be hypothesized that factors that could give rise to physicians' uncertainty about recommending complete diagnostic evaluation include physician confidence in screening, knowledge about the procedures that constitute complete evaluation, past experience in following up positive fecal occult blood test results, concern about cost and safety issues, and perceived patient preferences.[24–26] Unfortunately, data were not collected in this study to determine which, if any, of these factors were associated with physicians' reluctance to recommend complete evaluation. Further research is required to understand why physicians eschew recommending complete evaluation. Studies are also needed to determine how to increase the use of complete evaluation. In this regard, HMO PA/NJ has introduced a continuing medical education program for physicians to enhance the quality of care delivered to screening program participants.

The extent to which the observations reported here can be generalized may be limited by characteristics of the HMO, the affiliated physicians and subscribing members, and the screening program. It also should be acknowledged that chart audit data are limited in accurately reflecting physicians' recommendations to patients. □

Acknowledgments

Support for this study was provided by the National Institutes of Health (grants CA34856-06, CA06927, and RR05895) and by an appropriation from the Commonwealth of Pennsylvania.

The authors thank US Healthcare Inc for encouraging the conduct of research in its medical care delivery system. We specifically want to recognize Drs Robert Goodman, Jay Rosan, and Jeffrey Weiner for reviewing this manuscript. Assistance provided by the US HEALTHCARE CHECK staff was vital to the generation of study materials and delivery of interventions. A member of this staff, Robert McLaughlin, was particularly instrumental in identifying and tracking study subjects. We acknowledge Drs Paul Engstrom, Edward Lustbader, Mary Daly, Philip Bralow, and David Badolato for providing helpful critical commentary on our analysis. Finally, we extend our appreciation to the US Healthcare staff and to the HMO PA/NJ primary-care physicians for their cooperation.

The Epidemiology of Child Abuse: Findings from the Second National Incidence and Prevalence Study of Child Abuse and Neglect

Joseph C. Cappelleri, PhD, John Eckenrode, PhD, and Jane L. Powers, PhD

ABSTRACT

The epidemiology of child abuse was investigated with data from the Second National Incidence and Prevalence Study of Child Abuse and Neglect. A statistical comparison of incidence rates suggested that age, family income, and ethnicity were risk factors for both sexual abuse and physical abuse, but county metrostatus was not. Gender was a risk factor for sexual abuse but not for physical abuse. A logistic regression analysis showed that ethnicity, county metrostatus, and a gender-by-income interaction distinguished sexual abuse from physical abuse. (*Am J Public Health.* 1993;83:1622–1624)

Introduction

The Second National Incidence and Prevalence Study of Child Abuse and Neglect was mandated by Congress in 1984 (1) to assess the current national incidence and prevalence of child abuse and neglect and (2) to determine how the severity, frequency, and character of child maltreatment had changed since 1980 when the First National Incidence Study was conducted.[1–3] A more extensive analysis of these large-scale, nationally representative studies could provide valuable scientific knowledge on the scope and nature of child maltreatment and its impact on public health issues.[4–7]

Using data from the Second National Incidence Study, we sought to examine the impact of five key demographic factors—age at discovery, gender, income, ethnicity, and county metrostatus—on sexual abuse and physical abuse. In addition, using these variables, we compared the risk of sexual abuse with the risk of physical abuse. The latter analysis is similar to one previously conducted by Jones and McCurdy.[5] However, these investigators used unweighted data, whereas we used the appropriate sampling weights, which gave the correct estimates of the standard errors associated with the regression coefficients and hence were more reliable for hypothesis tests and confidence interval estimations. Emotional abuse has been excluded from our analyses because it was more difficult to define and measure.[8,9]

Methods

Study Design

Data for this study were collected between September 7 and December 6, 1986. A weighted multistage cluster probability sample was used.[2,3] A nationally representative sample of counties consisting of 28 county-level primary sampling units located in 19 states was selected. Cases were identified through Child Protective Services, as well as through other community professional agencies (e.g., hospitals, schools, day-care centers, social services, and municipal police).

Definitions

"Incidence rate" is defined as the number of new cases of maltreated children *reported* in 1986. Reported cases contain both official reports of abuse known to Child Protective Services and unofficial reports of abuse known to professionals and investigatory agencies other than Child Protective Services. The definition of sexual abuse included intrusion, molestation with genital contact, and other or unknown sexual abuse that was perpetrated or permitted by an adult caretaker, parent, or parent substitute. Unlike sexual abuse, physical abuse was not broken down into more specific forms of maltreatment, but was said to occur when a child suffered a physical injury as a result of actions by a parent or caretaker.

Statistical Analysis

First, we statistically evaluated each of the five potential risk factors for sexual abuse and physical abuse by comparing two given categories (subgroups) of a potential risk factor. Then, we quantified the odds of a child's being sexually abused relative to the odds of a child's being physically abused as a function of the five risk factors by performing a multivariate logistic regression analysis. The weighted results were generated by the WESVAR program[10] for the descriptive results and the WESLOG program[11] for the logistic regression results. All statistical tests were based on two-tailed tests at the .05 level of significance.

Results

Descriptive Analysis

The results showed that an estimated total of 133 619 children were reported as being sexually abused in 1986, which represents an estimated incidence rate of 2.11 per 1000 children. An estimated total of 311 524 children were reported as being physically abused in 1986, which represents an estimated incidence rate of 4.95 per 1000.

TABLE 1—Potential Demographic Risk Factors for Sexual Abuse and Physical Abuse

	Sexual Abuse				Physical Abuse

Urban–rural	0.44	1.29	−2.21	3.09	0.47	2.87	−5.94	6.38

Note. CI = confidence interval.
[a]The White category included Whites and Hispanics, the Black category included Blacks not of Hispanic origin, and the other category included all other ethnic groups (including American Indian, Alaskan Native, Asian, Pacific Islander).
[b]Practically speaking, this number can be increased to zero, because a negative incidence rate is not possible.
[c]Major urban counties included the 32 largest metropolitan areas in the country, urban counties included the other metropolitan areas, and rural counties included the remaining areas.
*$P \leq .05$.

Table 1 shows that, for both types of abuse, the five oldest age groups had a substantially higher rate of physical abuse than the birth-to-2-year-olds, although the older age groups did not differ statistically among themselves. Girls had a higher rate of sexual abuse than boys; physical abuse did not appear to vary by the child's gender. Family income was a significant risk factor for both physical abuse and sexual abuse. Whites were more likely to be identified as sexually abused than non-Black minorities. Black children were physically abused at a significantly higher rate than White children and children in "other" ethnic groups. Finally, there were no urban–rural differences in the rates of sexual abuse or physical abuse.

Logistic Regression Results

Table 2 shows the logistic regression results predicting the odds of sexual abuse relative to physical abuse. Compared with physical abuse, sexual abuse was more likely (1) for Whites than Blacks, (2) for girls than boys regardless of family income, and (3) for children residing in urban areas than for children

TABLE 2—Odds Ratio Estimates and 95% Confidence Intervals for Predicting the Likelihood of Sexual Abuse Relative to Physical Abuse

Risk Factor	Odds Ratio Estimates (Sexual Abuse Relative to Physical Abuse)	95% Confidence Interval of True Odds Ratio
Race (Black to White)	0.33*	0.25, 0.44
Sex (girls to boys)	3.74*	2.67, 5.24
Sex × income	0.44*	0.31, 0.63
Major urban to rural	1.37*	1.01, 1.86
Urban to rural	1.35*	1.01, 1.82
Family income (<$15 000 to ≥$15 000)	1.15	0.95, 1.38
Race (non-Black minorities to White)	0.81	0.47, 1.37
Age (birth–12 years old to 13–18 years old)	0.95	0.82, 1.10

Note. Fewer than 2% of the cases involved both sexual abuse and physical abuse. These cases were classified as sexually abused in the reported analysis.
*$P \leq .05$.

residing in rural areas. In addition, the somewhat higher risk of sexual abuse relative to physical abuse for girls varied by income, with a greater gender difference in risk for lower income families.

Discussion

In this paper we present data from the Second National Incidence and Prevalence Study of Child Abuse and Neglect regarding rates of physical and sexual abuse. We found that the rates of physical and sexual abuse varied as a function of the sociodemographic characteristics of the child and his or her family and that these characteristics helped distinguish between those children at risk for physical abuse and those at risk for sexual abuse. Some of our findings, such as the fact that low income was a significant risk factor for both forms of maltreatment, serve to confirm data reported in other studies. Other findings, such as the differential effect of gender as a function of income when the risk of sexual vs physical abuse is predicted, have not previously been reported.[8,12,13] Unlike the results of Jones and McCurdy,[5] our logistic regression findings showed that, relative to physical abuse, sexual abuse was more likely for Whites than for Blacks but not more likely for Whites than for other racial groups.

Although the data from the Second National Incidence Study have several major limitations (see Finkelhor and Hotaling for a critique[14]), they are the best available data from which to derive national estimates for the incidence of child abuse and neglect. These data also have value for advancing basic knowledge about child maltreatment and for informing public policy, particularly with regard to estimating the extent of the problem of child maltreatment beyond what is reported to official sources. The data may also help to dispel certain widely held assumptions about maltreatment, such as the assumption that younger children are at greater risk for abuse than older children. More extensive analyses of the data from both the Second and the First National Incidence Studies not only would help refine our current understanding of child maltreatment, but also would highlight aspects of study design that need improvement for future incidence studies. □

Activity, Inactivity, and Obesity: Racial, Ethnic, and Age Differences among Schoolgirls

Anne M. Wolf, MS, RD, Steven L. Gortmaker, PhD, Lilian Cheung, DSc, RD, Heather M. Gray, AB, David B. Herzog, MD, and Graham A. Colditz, MBBS, DrPH

ABSTRACT

Physical activity, inactivity, and obesity were assessed by questionnaire among a multiethnic sample of 552 girls in grades 5 through 12. Hispanics and Asians reported lower activity levels than other racial groups. Only 36% of the entire sample and less than one fifth of either Asians or Hispanics met the year 2000 goal for strenuous physical activity. Physical activity was inversely associated with age and age-adjusted body mass index. Obesity was unrelated to inactivity. (*Am J Public Health.* 1993; 83:1625–1627)

Introduction

Although studies have explored the frequency[1] and determinants[2] of children's participation in physical activities, racial/ethnic and age differences (elementary to high school) in activity levels have not been studied; also, the relationship between physical activity, sedentary behavior, and the prevalence of obesity in different racial/ethnic and age groups has not been examined. This study explored race-, ethnicity-, and age-related differences in activity, inactivity, and obesity among a multiracial sample of girls in grades 5 through 12 living in a low-to-medium income northeastern town.

Methods

A school-based survey was administered from February through May 1991 to 552 girls residing in Lynn, Mass. The ethnic composition of the study population (64.3% White, 15.4% Black, 11.2% Hispanic, 4.3% Asian, and 4.7% other/mixed) was representative of the school district. Elementary schools (grades 5 and 6), junior high schools (grades 7 and 8), and high schools (grades 9 through 12) contributed 29.5%, 37.1%, and 33.3%, respectively, of the study population. After active parental consent was obtained and dropouts and absentees were excluded, the estimated response rate among students who were eligible to receive the questionnaire was 78%.

Physical activity was self-reported on the Godin-Shepard Physical Activity Survey,[3] which has good 2-week test–retest reliability and construct validity among children.[4] The survey was modified by developing closed-ended options for frequency of participation (range: less than one to more than five times per week). A total exercise score was derived as follows:

$$\text{Total Exercise} = (\text{Frequency of Mild Exercise} \times 3) + (\text{Frequency of Moderate Exercise} \times 5) + (\text{Frequency of Strenuous Exercise} \times 9)$$

Height and weight were self-reported. Obesity was defined by age- and sex-appropriate reference data of body mass index (kg/m^2) at the 85th percentile.[5] Sedentary behavior or inactivity was assessed by number of hours of television viewed per day; six closed-ended categories (ranging from less than 1 hour to 9.5 hours per day) were used in these assessments.

Statistical Analysis Software[6] was used in conducting statistical analyses. Age, race, and age-adjusted body mass index were controlled for in these analyses. Indicator variables were used for racial/ethnic and age groups, with White and high school as the referent groups.

Results

The distribution of participants by age, body mass index, physical activity, and television use is shown for each racial/ethnic and age group in Table 1.

Physical Activity

Physical activity varied by ethnicity. Table 2 shows ethnic differences in physical activity adjusted for age. The other/mixed group reported the most activity; the largest proportion of the scores of this group were the result of strenuous exercise. After controlling for age, Asians and Hispanics reported 8.81 ($P < .01$) and 12.61 ($P < .0001$) fewer activity units, respectively, than did the referent group; a large proportion of the activity for both ethnicities involved mild exercise. Only 36.4% of the entire sample and less than

High school	183	24.5	39.29 (1.8)[b]	31.9	24.8	43.2

Note. The relationship between race/ethnicity and total exercise score was adjusted for age via multiple regression; the relationship between age and total exercise score was adjusted for race/ethnicity via multiple regression. Classification of race/ethnicity was missing for one girl.
[a]Defined as a body mass index equal to or greater than the 85th percentile for age in the general population using data from National Health and Nutrition Examination Survey I.[5]
[b]The referent was White high school student.

50% of most ethnic groups met the year 2000 objective for the nation for strenuous physical activity (Table 2).

Physical activity also varied by age (Table 2). The total activity level was 24% higher for elementary than for high school students. Total activity and strenuous activity decreased, and mild exercise increased, with age (Table 2). There was no interaction between age and race in their association with total exercise.

Inactivity

There were no grade-level differences in hours of television watched; however, racial/ethnic differences were observed (Table 1). Television viewing was not correlated with physical activity after adjusting for age (partial $r = -.015$, $P = .26$) or for age and race (partial $r = -.049$, $P = .40$). Although inactivity is simply the low end of the activity spectrum, activity and inactivity are separate domains from behavioral and analytical viewpoints.[7] Thus, we refer to inactivity independently from activity.

Obesity

There were strong racial/ethnic and age differences in prevalence of obesity; it was highest among Blacks and lowest among Asians. Body mass index (adjusted for age) was inversely associated with activity ($P < .0001$). There was no relationship between amount of inactivity (categorizing television viewing into five groups) and prevalence of obesity ($P = .47$ for trend): the least inactive girls were most obese, thus nullifying the trend. However, in evaluations excluding this group, an increased prevalence of obesity was observed with greater inactivity ($P = .04$ for trend).

Discussion

Our finding that 36% of all girls met the year 2000 goal for strenuous activity corroborates the report of the 1990 Youth Risk Behavior Survey.[8] Both studies report decreased strenuous activity among older girls.

Variation in total exercise between racial/ethnic groups may reflect cultural differences. In Hispanic and Asian cultures, strenuous physical activity may not be considered feminine, or there may be a greater emphasis on academics; however, we have no further information to support these explanations. Alternatively, culture may mediate activity level through the preference for obesity.[9]

Our data suggest that physical activity and strenuous activity decrease, while mild activity increases, with age. Decreased physical activity with age has been reported among both American and Scandinavian youths.[8,10] Activity may decrease in response to social or biological cues. As girls age, they may become more interested in appearance and pursue more sedentary social interests, or they may adopt sedentary, adult-modeled behavior patterns.[11]

Our findings do not corroborate previous reports of an association between television viewing and obesity,[7,12] except when we omit the group watching the least television, which included similar per-

centages of all racial/ethnic groups but was composed predominantly (40.9%) of high school students. The null finding may reflect a true lack of relationship, may be due to misclassification of inactivity level, or may be caused by obese girls reducing television viewing. We have no evidence for these different explanations.

Limitations of this study include self-reported data. The amount of daily television viewing reported in our study is consistent with some reports,[13] but the weekly average (mean = 26.6) is higher than in others.[7,12] Although our wording was similar to that used in national studies, differences in response could reflect a socioeconomic status lower than that of the general population.

Seasonal differences in physical activity may have influenced our results. In comparison with total activity level in other studies using the same measure, our scores were 28%[14] and 36% to 45%[4] lower in subjects of similar age. Our survey was administered in winter/early spring, which may partially explain the lower activity levels. Ethnic and age differences were detected despite lower overall levels of activity.

Because of a disproportionate amount of obesity-related disease among US minorities, it is essential in future studies to investigate the participation and perception of modifiable behaviors such as physical activity among different racial/ethnic groups. A better understanding of racial, ethnic, and age differences in activity level will permit more effective interventions focused on modifiable risk factors for disease. □

Health Promotion Conference to Be Held in February

The fifth annual conference on "The Art and Science of Health Promotion" will be held February 22 through 26, 1994, at the Broadmoor Resort in Colorado Springs, Colo. Sponsored by the *American Journal of Health Promotion,* the primary focus of the conference is bringing together the practitioners who represent the art of health promotion and the researchers who represent the science. Through this conference, the participants will explore both the art and science of health promotion and work toward bringing these two groups together.

In the past two decades, we have learned that social influences have a tremendous impact on health. Yet, if social influences are so powerful, why have most health promotion programs failed to recognize and protect against the negative social effects and harness the positive effects? At least two thirds of the conference's sessions will be devoted to this theme. The conference will profile organizations and communities that have already developed effective techniques and programs; present clusters of workshops on work and family issues, underserved populations, health care reform, and the concept of social ecology; and offer sessions on a wide range of research, practice, and ethical topics that represent the latest thinking in health promotion.

Past participants include benefits managers, clinical practitioners, consultants, dietitians, epidemiologists, geriatric wellness coordinators, health educators, health promotion specialists, industrial health managers, instructors, nurses, and physicians.

For more information contact the *American Journal of Health Promotion,* 1812 S Rochester Rd, Suite 200, Rochester Hills, MI 48307-3532; tel (313) 650-9600; fax (313) 650-9602.

Safety Behavior among Iowa Junior High and High School Students

Mario Schootman, MS, Laurence J. Fuortes, MD, Craig Zwerling, MD, PhD, MPH, Mark A. Albanese, PhD, and Carol A. Watson, PhD

ABSTRACT

The goal of this study was to determine demographic factors associated with reported safety behavior by studying 2250 Iowa junior high and high school students via a self-administered questionnaire. Students attending rural schools used front seat belts and helmets less frequently than urban students. Seat belt and helmet use and swim safety decreased dramatically with age. Occurrences of driving or riding while drunk or high increased with age. Boys were less likely than girls to wear back seat belts and moped helmets and to check water depth before diving. Possession of a driver's license was not independently associated with any of the safety behaviors. (*Am J Public Health.* 1993;83:1628–1630)

Introduction

Many injuries that occur among 10- to 19-year-olds are preventable. Using seat belts in cars reduces the risk of death in a crash by about 41%.[1] Using helmets on bicycles reduces the risk of head injury by 85%.[2] However, both safety behaviors are least common among those at highest risk (e.g., teenagers) for being involved in crashes.[3] If behaviors associated with an increased risk of injury are to be changed, it is important to know in which group the need for intervention is greatest. The purpose of this study was to determine demographic factors associated with safety behavior among junior high and high school students.

Methods

Data Collection

Data for this study were collected from October 1990 through April 1991 as baseline data for evaluation of a prevention program called the Traumatic Injury Prevention Strategy. This program aims at preventing head and spinal cord injuries among adolescents by increasing the use of preventive measures such as seat belts and bicycle helmets. A self-administered questionnaire measured safety behaviors before the intervention.

Teachers at participating schools who requested that their students become familiar with the Traumatic Injury Prevention Strategy program distributed the baseline questionnaire in a required class. At least 50 students from each school filled out the survey instrument.

Variables

Students were asked about the frequency of their seat belt and helmet usage, swim safety behavior, and driving and riding under the influence of alcohol or drugs. Students answered either yes or no to questions regarding driving and riding while drunk or high. Responses to the other questions were provided on a 5-point scale (never, seldom, sometimes, often, or always).

Demographic variables potentially associated with safety behavior include age, gender, possession of a driver's license, and school location. School location was either urban or rural (schools defined as urban were located in an incorporated area of at least 2500 people).

Stepwise logistic regression was used to determine factors associated with self-reported safety behavior among students. Reported safety behaviors were dichotomized in two categories: often/always or sometimes/seldom/never.

Results

A total of 2250 students from 41 junior high and high schools participated in the baseline survey. The average school had 290 students, with 55 viewing the Traumatic Injury Prevention Strategy program and participating in the study. Table 1 displays the number and percentage of students according to their gender, school location, possession of a driver's license, and age.

Seat belt usage was more prevalent in the front seat (54%) than in the back seat (15%) of a car (Figure 1). Helmets were most often used on all-terrain vehicles and snowmobiles (34%). Bicycle helmets were rarely used (2%).

The results of the logistic regression analysis are presented in Table 2. With the exception of wearing a helmet while skateboarding, the percentage of students who reported often or always engaging in each safety behavior decreased with age after adjustment for other independent variables. The increase in percentage per year was greater for having driven while drunk or high than for having been in a car with

Alcohol and drugs			
Driving a car	...	...	2.25 (1.82, 2.78)
Riding with friend	...	...	1.46 (1.39, 1.54)

Note. Ellipses indicate that the variable is not included in the model.
[a]For the sex variable, female was used as reference; for location, urban was used as reference.
[b]Although 1 is included in the confidence interval, the likelihood ratio test is significant.

a friend who was drunk or high. Since students have had more opportunity to display the latter two behaviors with increasing age, rates of reported driving while drunk or high by person-years in different age groups were calculated. For driving under the influence of alcohol or drugs, the rate increased with age, while no increase was seen for riding with a friend who was drunk or high.

Students enrolled in rural schools reported wearing seat belts less often in the front seat of a car, and they were less likely to wear helmets on mopeds, all-terrain vehicles and snowmobiles, and bicycles. Male students reported wearing seat belts in the back seat of a car less often than did their female counterparts. Also, they were less likely to wear helmets on mopeds and to check water depth before diving. Having a driver's license was not associated with any of the reported safety behaviors after controlling for the effect of age. Interactions between the included demographic variables did not contribute significantly to the prediction of any of the reported safety behaviors.

Discussion

Students attending rural schools were less likely to wear seat belts while riding in the front seat. This finding is of concern since injury rates on rural roads are higher than on urban roads.[4] As in other studies,[5] age was associated with almost all safety behaviors.

The ultimate goal of injury epidemiology is to intervene in the causal pathway of the occurrence of injuries through preventive measures. Groups with the highest risk of a particular type of injury and the lowest rates of safety behavior are likely to yield the greatest benefits from interventions; however, the results of such interventions depend on the time at which they take place in a person's life.[6] Children progress through different developmental stages at which specific types of prevention can be aimed. Adolescence is characterized by increased risk taking, peer pressure, and feelings of invulnerability. Because it has been hypothesized that educational programs may, at times, have an effect opposite of that intended,[7] it is suggested that children be targeted before they reach adolescence.[8,9]

On the other hand, adolescents are currently not engaging as frequently in safety behavior as are younger children, and they are clearly at highest risk for in-

juries involving motor vehicles.[10] Therefore, targeting prevention by educating children before they reach adolescence may be more efficacious but would not be sufficient to reduce mortality from motor vehicle and recreational injuries in the group currently at greatest risk. Both age groups should be targeted, and educational interventions need to be rigorously evaluated to determine optimal prevention strategies. □

The Choice of Weapons in Firearm Suicides in Iowa

ABSTRACT

This study reports the types of firearms used in firearm suicides in Iowa and tests the hypothesis that the use of handguns, rifles, and shotguns in such suicides reflects the availability of these weapons. The percentage of firearm suicides involving handguns increased from 36.6% in 1980 through 1984 to 43.3% during 1990 and 1991. In both time periods, the use of handguns was more likely than would be expected from their household prevalence. Our data suggest that handguns are disproportionately represented among firearm suicides and that this overrepresentation has increased during the last decade. (*Am J Public Health.* 1993;83:1630–1632)

Craig Zwerling, MD, PhD, MPH, Charles F. Lynch, MD, PhD, Leon F. Burmeister, PhD, and Ulrike Goertz, MS

Introduction

In 1988, 18 181 firearm suicides accounted for 53% of the firearm deaths in the United States,[1] outnumbering firearm homicides by almost 5000. Firearms accounted for 60% of all suicides.[1] However, relatively little is known about the types of firearms used in suicides. Nationwide, the specific type of weapon used is not recorded on death certificates in two thirds of firearm suicides.[1] The three studies that have examined the choice of weapons in firearm suicides focused on urban counties.[2–4]

We report on the types of firearms used in firearm suicides in a rural state, Iowa, from 1980 through 1991. In addition, we test the hypothesis that the observed frequency of use of handguns, rifles, and shotguns in firearm suicides reflects the availability of each of these weapons.

Methods

For 1980 through 1984, data on suicides were drawn from the Iowa Master Mortality File maintained by the State Health Registry.[5] For 1990 and 1991, data were drawn from the computerized records of the Iowa state medical examiner.

Data on the prevalence of handguns, rifles, and shotguns in households were derived from the general social survey database of the National Opinion Research Center, a national probability sample of adults living in households in the United States.[6] The Northwest Central census division, which includes the states of Iowa, Minnesota, Missouri, North Dakota, South Dakota, Nebraska, and Kansas, was used in estimating Iowa data. Surveys conducted in 1980, 1982, and 1984 yielded estimates based on interviews of 500 households. Combining the surveys from 1990 and 1991 yielded estimates based on 256 households.

Respondents were asked, "Do you happen to have in your home any guns or revolvers?" Those answering "yes" were asked a follow-up question: "Is it a pistol, shotgun, rifle, or what?" Answers were

This paper was accepted March 25, 1993.

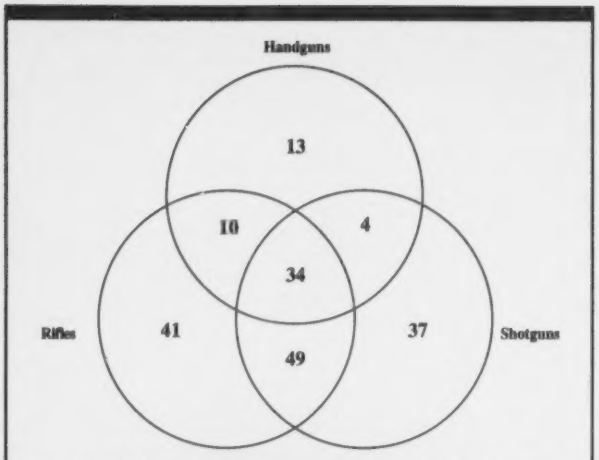

FIGURE 1—Venn diagram showing the distribution (absolute numbers) of guns in the 188 households owning guns in the Iowa Northwest Central census division, 1980 through 1984.

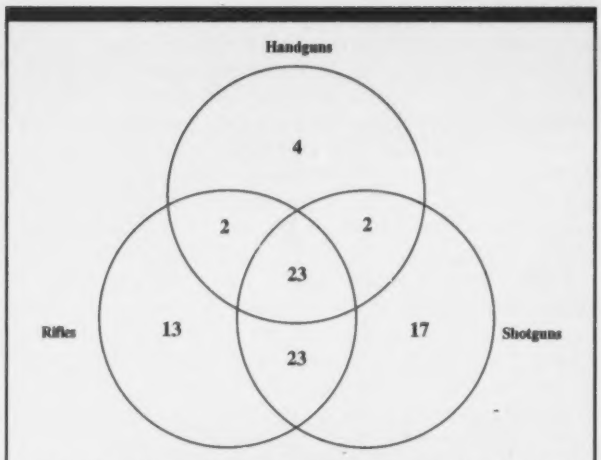

FIGURE 2—Venn diagram showing the distribution (absolute numbers) of guns in the 84 households owning guns in the Iowa Northwest Central census division, 1990 through 1991.

coded yes or no separately for pistols, shotguns, and rifles.[7]

For 1980 through 1984 and 1990 to 1991, 37.6% and 32.8% of respondents, respectively, reported having guns at home. The distribution of type of weapons is shown in Figures 1 and 2. To test the hypothesis that the choice of firearm type in suicides reflected the number of households with that type of weapon, we assumed that in households possessing more than one type of weapon, each was equally likely to be used.[3] We used these proportions to compute expected values for use in firearm suicides. We calculated ratios by dividing the percentage of suicides involving a specific weapon by the expected percentage based on the prevalence of that weapon in the regional population using the National Opinion Research Center data (suicides/weapon prevalence). We calculated 95% confidence intervals using the logarithmic method.[8]

Results

Death certificate records revealed that 877 firearm suicides were committed in Iowa during 1980 through 1984. For 92.5% of them, the type of firearm used was recorded. Handguns were used in 297 suicides (36.6%); shotguns, in 335 (41.3%); and rifles, in 179 (22.1%). The choice of weapons in firearm suicides differed by sex (Table 1). We found the following ratios of suicides/weapon prevalence: 2.20 (95% CI = 1.57, 3.05) for handguns, 1.04 (95% CI = 0.85, 1.25) for shotguns, and 0.51 (95% CI = 0.41, 0.60) for rifles.

Medical examiner's records revealed 292 firearm suicides in 1990 and 1991. For 96.9% of them, the type of firearm used was recorded. Handguns were used in 124 suicides (43.8%); shotguns, in 113 (39.9%); and rifles, in 46 (16.3%). Again, the choice of weapons differed by sex (Table 1). We found the following ratios of suicides/weapon prevalence: 2.69 (95% CI = 1.63, 4.45) for handguns, 0.90 (95% CI = 0.68, 1.19) for shotguns, and 0.41 (95% CI = 0.28, 0.60) for rifles.

A comparison of the years 1990 and 1991 and the years 1980 through 1984 revealed that the proportion of firearm suicides involving handguns increased from 36.6% to 43.8% ($P = .03$ using the normal approximation to a binomial distribution), even though there was no change in the prevalence of handguns in the region (16.7% in 1980 through 1984 and 16.3% in 1990 and 1991).

Discussion

Federal Bureau of Investigation data show that handguns account for a disproportionate share of firearm homicides (75% in 1988).[1] However, the equivalent national data have not been available to assess the contribution of handguns to firearm suicides. In fact, the largest study of the role of handguns in firearm suicides was limited to one urban county (Sacramento County, California). In that study, Wintemute et al.[3] found that, relative to their prevalence in Pacific census region households, handguns were twice as likely to be involved in firearm suicides.

Our study provides the first statewide data to address this issue. We found that handguns accounted for 2.20 to 2.69 times

TABLE 1—Firearm Suicides by Type of Weapon, State of Iowa, 1980 through 1984 vs 1990 through 1991

	Handgun		Shotgun		Rifle		Total	
	No.	%	No.	%	No.	%	No.	%
1980–1984 ($\chi^2 = 28.1$, $df = 2$, $P < .001$)								
Male	248	33.7	318	43.3	169	23.0	735	100
Female	49	64.5	17	22.4	10	13.2	76	100
Total	297	36.6	335	41.3	179	22.1	811	100
1990–1991 ($\chi^2 = 14.8$, $df = 2$, $P < .001$)								
Male	107	40.7	111	42.2	45	17.1	263	100
Female	17	85.0	2	10.0	1	5.0	20	100
Total	124	43.8	113	39.9	46	16.3	283	100

as many suicides as would be predicted by their estimated prevalence in households in our census region. This confirms the results of Wintemute et al.[3] and extends them to a rural region where handguns are much less prevalent (17% in the Northwest Central census region vs 35% in the Pacific census region). It also suggests that the role of handguns in firearm suicides may be increasing.

The use of National Opinion Research Center general social survey data to estimate the prevalence of types of firearms in households has potential weaknesses. First, we assumed that in households with multiple types of guns, any type was equally likely to be used in a suicide. We agree with Wintemute et al.[3] that this is the most reasonable assumption, but other assumptions could decrease the apparent role of handguns. One study of adolescent suicide victims[9] who had both handguns and long guns at home showed that they were slightly, but not statistically significantly, more likely to use a handgun. Second, some[10] have argued that gun owners underreport ownership in surveys. However, survey respondents rarely refuse[11] to answer questions about gun ownership, and a recent validation study[12] suggests that 97% of registered owners report ownership.

Our data suggest that handguns are disproportionally represented among firearm suicide weapons and that the overrepresentation has increased in the last decade. The availability and ease of use of handguns may make them particularly attractive in impulsive suicides. Thus, restrictions on the availability of handguns might decrease suicide rates, particularly among young people, who are most likely to act impulsively. Recent studies support this argument. Loftin et al.[13] found a 23% drop in gun-related suicides in the District of Columbia after the introduction of restrictive handgun licensing, and two recent case–control studies[9,14] showed an association between suicide and the presence of a gun in the home. Taken together, these results suggest that handgun restrictions might well lead to a reduction in suicide rates. □

The Effects of Resistance Strategies on Rape

Janice M. Zoucha-Jensen, MSW, and Ann Coyne, PhD

ABSTRACT

This investigation sought to clarify which resistance strategies were associated with rape avoidance and at what cost. Data were gathered from initial and supplemental police reports about 150 sexual assault victims, ages 16 and older, who were assaulted between June 1, 1988, and May 31, 1989, in Omaha, Neb. Although this analysis could not determine causality, it did indicate that forceful verbal resistance, physical resistance, and fleeing were all associated with rape avoidance, whereas nonforceful verbal resistance and no resistance were associated with being raped. Further, women who used forceful resistance were no more likely to be injured than women who did not resist. (*Am J Public Health.* 1993;83:1633–1634)

Introduction

A rape is reported in the United States every 6 minutes. Over the last decade, the rate of reported rapes increased four times as fast as the overall crime rate.[1] Although this statistic is alarming, it substantially underrepresents the true incidence of rape. Government estimates suggest that "for every rape reported to police, 3 to 10 rapes are not reported."[2(p3)] Because of these startling statistics, extensive research has been done in the area of rape prevention. However, past research has failed to identify what types of resistance strategies most effectively prevent rape and at what cost. This has led to conflicting advice being offered to women.

Siegel et al.'s interview study, which used randomly selected community residents, found that "resistance particularly verbal, reduces the probability of sexual contact. Physical resistance, on the other hand, is associated with increased likelihood of contact."[3(p31)] Several other researchers reported similar findings with samples of selected subjects who reported the rape to police or sought rape crisis services.[4–6] However, some researchers[7–13] who sampled similar populations found just the opposite to be true. Bart and O'Brien found that "strategies associated with avoidance were fleeing or trying to flee, yelling, and using physical force."[7(p84)]

Because past research about the effectiveness of various types of resistance has been inconclusive, this research was conducted to determine which resistance strategies were associated with rape avoidance and whether physical resistance in particular was associated with additional physical injury. It was hypothesized that more forceful resistance would be associated with rape avoidance but physical resistance would be associated with additional physical injury.

Methods

Data were collected from the Omaha, Neb, Police Department's initial and supplemental reports. The sample consisted of 150 women, aged 16 and older, whose sexual assault occurred between June 1, 1988, and May 31, 1989, and was reported to the Omaha Police Department. Nebraska law requires medical personnel to report to the police any injury sustained because of violence. The sample thus consisted of women who themselves reported the assault to the police or who sought medical attention and whose assault was then reported to the police by medical personnel. It is likely that attacks resulting in injuries, attacks by strangers, and attacks in which resistance was less successful were probably overrepresented in this sample.[8] Despite this inherent bias, however, a finding of a positive association between resistance and rape avoidance with women in this sample should allow us to infer that a similar association would hold for rape attempts not reported to police.

The independent variable, resistance strategy, was defined as any action taken to ward off the attack. This variable was divided into five categories: no resistance; nonforceful verbal resistance (pleading, crying and/or assertively refusing); forceful verbal resistance (screaming and/or yelling); physical resistance (wrestling/struggling, pushing, striking, biting, and/or using a weapon); and fleeing (running, walking away, and/or fleeing in a car). In cases in which several types of resistance were attempted, this variable was coded as the most forceful resistance strategy attempted.

The dependent variables were outcome of the assault and additional physical injury. Outcome of the assault was divided into two categories, raped and avoided rape. "Raped" was defined as having sustained penile, oral, or digital penetration or penetration by an instrument, in all cases under force or threat of force. "Avoided rape" was defined as having sustained no penetration. "Additional physical injury" was also divided into two categories, injured and not injured. "Injured" was defined as having sustained any apparent injury or complained of an injury. "Not injured" was de-

TABLE 1—Resistance Strategy by Outcome of the Assault (n = 149)

Resistance Strategy	Outcome of the Assault[a]	
	Raped, % (n = 97)	Avoided Rape, % (n = 52)
No resistance	93.5	6.5
Nonforceful verbal resistance	95.8	4.2
Forceful verbal resistance	50.0	50.0
Physical resistance	45.5	54.5
Running/fleeing	55.0	45.0

[a] $\chi^2(4, n = 149) = 22.93$, $P < .001$.

fined as not having sustained any apparent injury and not complaining of an injury.

Results

Of the 150 women in the sample, 64.7% were raped and 35.3% avoided rape, with 46.7% incurring an additional physical injury. Physical resistance was the most frequently selected resistance strategy (44.3%).

We analyzed resistance strategy by outcome of the assault using a chi-square test. Forceful verbal resistance, physical resistance, and fleeing were all associated with rape avoidance. No resistance and nonforceful verbal resistance were associated with being raped (χ^2 [4, n = 149] = 22.93, $p < .001$) (see Table 1).

We analyzed resistance strategy by additional physical injury using a chi-square test. There was no significant relationship between the two variables.

Discussion

This study supports prior research that found an association between physical resistance and rape avoidance.[7–13] It also contradicts other prior research that found an association between less forceful verbal resistance (pleading, crying, etc.) and rape avoidance.[3–6] This study in fact found a negative association between nonforceful verbal resistance (pleading and crying) and rape avoidance but a positive association between forceful verbal resistance (screaming or yelling) and rape avoidance.

The findings of this study, in combination with some past research, provide professionals who are responsible for public health education with direction in planning public educational programs. These findings also counter some prior research on resistance strategies, research that has resulted in inaccurate advice to women to use only nonforceful verbal resistance, or no resistance at all, if faced with a sexual assault. Those types of resistance strategies were shown in this study to be associated with being raped, not with rape avoidance, and they did not reduce the incidence of physical injury.

Because of the contradictory results of past studies, additional research on rape prevention strategies is needed. Special attention should be paid to the temporal sequencing of resistance strategies, outcome, and additional physical injury so that these relationships can be understood. In addition, resistance strategies should be measured so that essentially different strategies are not artificially combined together. For example, if screaming and pleading had been combined into one measure called "verbal resistance," important differences would have been lost. Lastly, future research needs to include women who did not seek medical attention for their injuries or report the assault to the police, women who were not injured, and women who were assaulted by people they knew. □

American Journal of Public Health

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

An Outbreak of Hepatitis A among Health Care Workers: Risk Factors for Transmission

ABSTRACT

Objectives. The purpose of this study was to investigate a nosocomial outbreak of hepatitis A that occurred in the burn treatment center of a referral hospital.

Methods. Retrospective cohort and case-control studies were performed to determine acquisition rates and risk factors for transmission. Adjusted infection rates were calculated by week of exposure. A case-control study was conducted to determine potential mechanisms for nosocomial acquisition. Recently infected health care workers were defined as case patients; exposed, serosusceptible health care workers without infection served as controls.

Results. The outbreak of hepatitis A affected 11 health care workers and 1 other burn patient (1 secondary patient case). All 11 health care workers became ill after the admission of a man and his 8-month-old son who developed hepatitis A while in the hospital. The cumulative incidence risk ratio was elevated for health care workers caring for either the infant or the father during the same week of exposure. The case-control study implicated the behavior of eating on the hospital ward as the single most important risk factor for infection.

Conclusion. Inadequate handwashing and subsequent oral contamination appear responsible for the outbreak. Hospitals may witness other institutional outbreaks if health care workers regularly eat on the wards. (*Am J Public Health.* 1993;83: 1679–1684)

Bradley N. Doebbeling, MD, MS, Ning Li, MB, MS, and Richard P. Wenzel, MD, MSc

Introduction

Nosocomial outbreaks of hepatitis A are relatively uncommon. Several food-related epidemics have been reported.[1,2] Most nosocomial outbreaks have involved exposure either to an asymptomatic infant or to a young child, typically after the transfusion of blood from an asymptomatic donor.[3–8] Occasionally, outbreak clusters have been reported after contact with an older child or adult with vomiting, diarrhea, or fecal incontinence.[9–14] Several large outbreaks in neonatal intensive-care units have been reported recently.[4,5,7,8] Despite extensive investigations, most previous reports failed to identify significant risk factors for nosocomial transmission, other than associated care of the infected individual. Rosenblum and colleagues[8] recently reported an outbreak of hepatitis A in a neonatal intensive-care unit, implicating the behaviors of drinking beverages in the unit and failure to wear gloves routinely as risk factors for transmission to health care workers.

We report here the first nosocomial outbreak of hepatitis A in a burn treatment center. The outbreak occurred between January and March 1990 in a tertiary-care hospital. A 32-year-old man and his 8-month-old son were admitted to the burn treatment center on December 9, 1989, after each had sustained large body surface area burns in a house fire, 70% and 40%, respectively. On January 8, 1990, the father became jaundiced, and both were found to have acute hepatitis A infections. Despite institution of appropriate isolation precautions,[15] 11 health care workers and 1 other burn patient became clinically ill with hepatitis A. We undertook an epidemiologic investigation to identify important risk factors for transmission in the hospital. Our investigation is the subject of this report.

Background

The hospital is a 900-bed referral center with a 16-bed burn treatment center. The typical nursing staff to patient ratio on the burn treatment center is approximately 1:3, although it varies depending on the acuity of the patient and the time of day. Health care workers regularly assigned to the burn treatment center often eat in the staff lounge or in a charting room, located approximately 15–50 feet from most of the patient rooms (Figure 1). Staff food is stored in a refrigerator in a designated staff food room, the staff lounge, or occasionally in the patient nourishment room. Infants and young children with burns are allowed to play in a playpen and eat beside the desks in the center of the burn treatment area. Additionally, outpatients with burns are routinely seen in follow-up on the ward and often bring in snack foods to share with the burn treatment personnel. Two sinks are located at the entrance to the center, and hand-washing is strongly encouraged

Bradley N. Doebbeling and Richard P. Wenzel are with the Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, Iowa. Richard P. Wenzel is also with the Program of Epidemiology, The University of Iowa Hospitals and Clinics. Ning Li is with the Department of Preventive Medicine and Environmental Health, Division of Biostatistics, The University of Iowa College of Medicine.

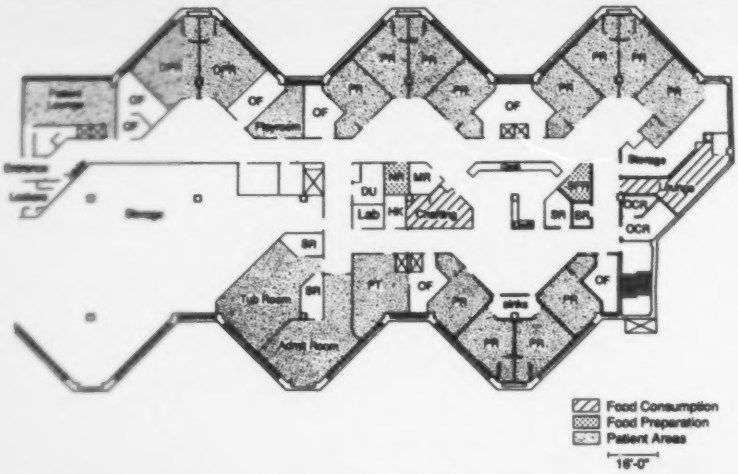
This paper was accepted April 26, 1993.

Editor's Note. See related editorial by Mosley (p 1664) in this issue.



Note. Staff members consumed food (hatched pattern) in the staff lounge, charting room, and occasionally in individual offices (OF). Food storage and preparation areas (dotted pattern) for the staff members included the staff food room (SFR), patient nourishment room (PNR), and staff lounge. Patient care areas (shaded) include sinks in each single and double patient room (PR and DPR, respectively). Other abbreviations include dirty utility (DU) room, medication room (MR), housekeeping (HK), physical therapy (PT), supply rooms (SR), and on-call rooms (OCR).

FIGURE 1—Floor plan of the burn treatment center.

on entering and leaving the ward with a display of prominent signs.

Methods

Epidemic Investigation

Selected burn treatment personnel and the burn patient with the secondary case of hepatitis were interviewed to determine potential common exposures and risk factors. The burn treatment center's charting room, staff lounge, refrigerators, sinks, ice machine, nourishment room, hydrotherapy room, rest rooms, water supply, and all patient care areas were inspected by members of the hospital epidemiology staff.

Screening. All health care workers assigned to the center in the prior 6 weeks (n = 154), all inpatients at the time of identification of the outbreak on February 9, 1990 (n = 12), and all patients discharged in the previous month (n = 45) were contacted and offered the option of screening with liver function tests and a serologic test for hepatitis A virus immunoglobulin M antibody (IgM anti-HAV test) (enzyme immunoassay, Abbott Laboratories, Chicago, Ill). Additionally, all food preparation workers in the hospital and the dietary services staff working on the burn center (n = 119) were contacted and similarly screened. All exposed employees of the burn treatment center who were IgM anti-HAV negative were tested for total anti-HAV antibody (anti-HAV, Abbott). A repeat IgM anti-HAV test was obtained for all consenting exposed health care workers regularly assigned to the burn treatment center 6 weeks later (n = 37) to determine whether seroconversion had occurred despite prophylaxis.

Case definition. A health care worker was defined as exposed if he or she had direct patient contact on the burn center in the 6 weeks (December 28, 1989, to February 7, 1990) before the outbreak. A preliminary case definition required elevation of serum levels of one of the liver transaminases to twice the upper limit of normal or symptoms consistent with acute HAV infection. Final inclusion as a case subject required a positive IgM anti-HAV titer, with or without clinical symptoms. A susceptible control subject was an exposed health care worker who tested negative for anti-HAV and who was in one of the same occupational categories as the health-care-worker case subjects (n = 60). Individuals with incomplete test results or prior immunity were excluded from further analysis.

Immunoprophylaxis. All asymptomatic health care workers in the burn treatment center who had contact with the index cases, all current patients, and all patients discharged in the previous month were contacted and offered immunoglobulin immunoprophylaxis. Health care workers were informed that the efficacy of immunoglobulin immunoprophylaxis has been demonstrated only when it is given within 2 weeks of exposure. Additionally, regional exchange nurses temporarily assigned to the burn treatment center to cover staffing shortages and all new patients admitted for the subsequent 6 weeks were offered immunoglobulin. All close contacts of those persons who were clinically ill or who had elevated liver transaminases were contacted to be screened and offered immunoglobulin. Consenting exposed individuals were given a single dose of immunoglobulin 0.02 ml/kg (Gamastan, Cutter Biologicals, West Haven, Conn) intramuscularly in the deltoid muscle. All case subjects were contacted by telephone 4 months later to determine whether any symptomatic secondary cases had occurred among their family members or close contacts.

Four burn treatment center nurses had been "pulled" to staff four other intensive-care units in the 48 hours before they became clinically ill. The patients for whom they cared and health care workers in close contact with the infected nurses were contacted and offered immunoglobulin prophylaxis.

Index cases investigation. The source of the initial index cases was investigated by interviewing the adult index case patient and his family members regarding potential risk factors and any possible common sources of exposure to hepatitis A before admission to the hospital. The Iowa State Health Department inspected a single family day-care home that cared for the index infant and six other children before the outbreak. Serum was obtained for an anti-HAV test from five of the six children, the babysitter, and family members of the babysitter. However, a sample could not be obtained from one of the children. Additionally, blood bank records were reviewed to determine the individuals donating blood to the two index case patients. None of the donors had given blood to both patients; all were contacted and asked to report any clinical illness in the 2 months before their donations.

Patient care study. A retrospective cohort study of health care workers was performed to evaluate the risk of infection associated with caring for the patients with the index cases. Nursing care assignments for the 6 weeks before the period of the peak incidence were examined to determine which nursing personnel had been

exposed to the index case patients. The study population included nurses and nursing students working in the burn treatment center during the 6-week period. Serosusceptible nurses caring for either of the index case patients were classified as exposed if assignment to one of the index patients occurred at least 2 weeks before the development of illness by the health care worker. Adjusted infection rates by week of exposure were calculated and were stratified by the number of shifts worked with either or both of the patients. Cumulative incidence ratios (relative risk ratios) were also calculated by week of exposure to either index patient.

Risk factor study. A case–control study was performed to evaluate behavioral risk factors and common exposures among health care workers for development of hepatitis A infection. A 50-item self-administered questionnaire was developed to assess potential risk factors for hepatitis A infection such as patient care practices (e.g., hand-washing, glove use, providing hydrotherapy, specific types of care of infants and adults), personal habits while working (e.g., eating, drinking, smoking, biting fingernails), any group exposures (e.g., potlucks, shared meals, dining out), environmental exposures, and specific food items eaten while at work. The questionnaire was pretested, revised, and then mailed to all 154 health care workers assigned to work in the burn treatment center in the 6 weeks before the outbreak's peak. All questionnaires were identified only by a confidential study number known to the investigators. Three sequential mailings of the questionnaire, which were followed by telephone contacts, were used to improve the response rate.

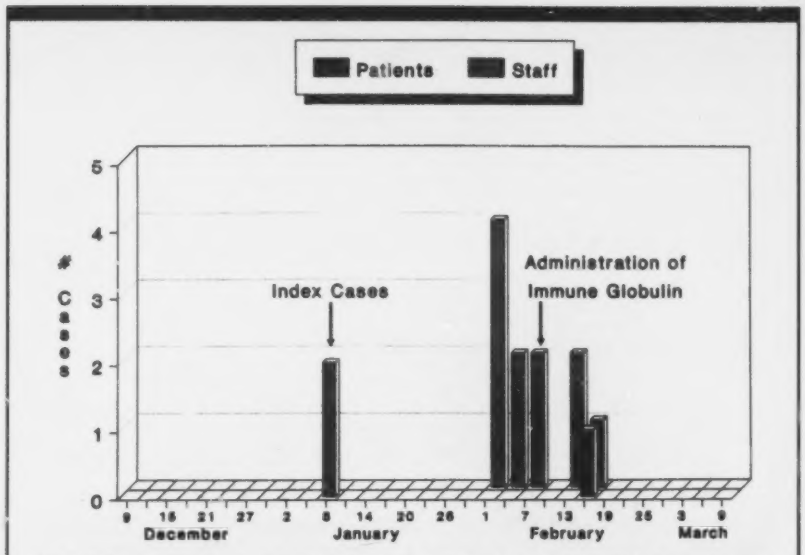
Statistical Methods

The statistical analyses included the use of the Mantel-Haenszel chi-square statistic, Fisher's two-tailed exact test, and odds ratios with 95% confidence intervals for all significance testing.[16] For the tables with zero entries, 0.5 was added to each cell; the Mantel-Haenszel estimator of the odds ratio and the test-based confidence interval were determined. Stepwise logistic regression was conducted by using SAS[17] to evaluate all variables that were identified by the univariate approach ($P < .10$). The significance level was set at .05. All P values reported are two-tailed.

Results

The IgM anti-HAV test was positive in the adult index case patient 1 month after admission. His asymptomatic 8-month-old son was also IgM anti-HAV positive at the same time. Serologic tests for hepatitis A (IgM-specific and total anti-HAV antibody) and liver function tests for both patients had been negative on admission. At the time of the investigation, no additional blood samples were available for antibody testing from the first month of the patients' hospitalization. Neither patient had vomiting or diarrhea. Inspection of the burn treatment center revealed sinks and dispensers for hand-cleansing agents located in each room, and all were found to be in good repair. Boxes of gloves and gowns and masks were readily available in each patient's room. All burn treatment personnel were asked to refrain from eating or drinking on the ward after identification of the outbreak.

A total of 154 health care workers were identified as having been exposed to patients on the burn treatment center in the 6 weeks before the health care workers became ill. Serologic tests for anti-HAV antibody in all consenting exposed workers demonstrated that only 8.7% of the 126 workers screened had detectable immunoglobulin G antibody to the hepatitis A virus. Three health care workers with clinical hepatitis A infection and the secondary case patient were initially seronegative for IgM anti-HAV antibody despite symptoms and elevated hepatic transaminases, but subsequently became seropositive in 5 to 7 days.

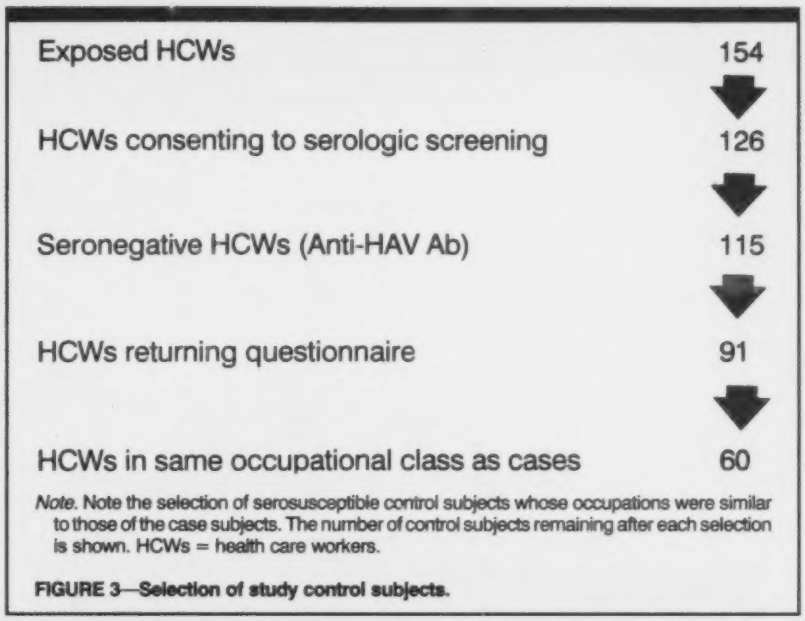


Note. Although the exact date of onset in the infant is uncertain, both index cases are represented at the date of onset of clinical illness in the adult. The single patient represented by the dark bar in February signifies the only secondary patient case. Not shown are the asymptomatic mother of the infant and an asymptomatic household contact of one of the nurse cases whose date of seroconversion is unclear. Note the incubation period of approximately 1 month among the health care workers.

FIGURE 2—Epidemic curve of an outbreak of hepatitis A on a burn treatment center.

Eventually a total of 11 health care workers developed IgM anti-HAV antibody, and all became clinically ill (Figure 2). Two required hospitalization for dehydration. The infection rates among serologically defined susceptible individuals ranged from 14% (7 of 50) among staff nurses and nursing assistants to 33% (2 of 6) among ward clerks and 67% (2 of 3) among nursing students. All case subjects had contact with the infant, whereas only 8 of 11 case subjects (73%) also had contact with the father. The 32-year-old mother of the index infant was also seropositive for IgM anti-HAV antibody, but remained asymptomatic. No symptomatic secondary cases occurred in close contacts or family members of the infected case subjects. The mother of the child was seropositive when checked in early February, although she was asymptomatic. One asymptomatic seroconversion occurred after prophylaxis with immunoglobulin in the fiancé of one of the nurse case subjects. None of 37 seronegative health care workers whose serology was rechecked at 4 to 6 weeks developed anti-HAV antibody.

Importantly, four cases of hepatitis A occurred in the county of residence of the infant and his father during November 1989, followed by 8 and 17 cases, respec-



Note. Note the selection of serosusceptible control subjects whose occupations were similar to those of the case subjects. The number of control subjects remaining after each selection is shown. HCWs = health care workers.

FIGURE 3—Selection of study control subjects.

TABLE 1—Hepatitis A among Health Care Workers in a Burn Treatment Center, January–February 1990: A Case–Control Questionnaire Study on Risk Factors

Exposure Variable[a]	Case Subjects (n = 11) Yes	Case Subjects (n = 11) No	Control Subjects (n = 60) Yes	Control Subjects (n = 60) No	Odds Ratio	95% CI[b]
Eating food on the burn center (BC) (frequently vs occasionally or never)	10	1	24	34	14.2	2.49, 80.50
Bringing in snacks to share in prior 6 weeks	7	4	10	50	8.8	2.44, 31.34
Eating snacks brought in by coworkers	10	1	36	24	6.7	0.99, 44.48
Close contact with mother of infant	2	9	2	58	6.4	0.99, 41.95
Providing hydrotherapy	9	2	26	34	5.9	1.33, 26.13
Spending ≥3 hours daily with BC patients	9	2	27	33	5.5	1.23, 24.62
Working in the tub room	9	2	29	31	4.8	1.06, 21.88
Care of infants: playing[c]	11	0	52	8	3.7	0.20, 69.23
Eating food from the common refrigerator	9	2	32	28	3.9	0.85, 18.34
Drinking coffee prepared on the BC	8	3	26	34	3.5	0.88, 13.78
Care of infants: holding/carrying[c]	11	0	53	7	3.2	0.17, 60.55
Eating at a BC potluck	3	8	9	51	2.1	0.48, 9.43
Eating out with coworkers in prior 6 weeks	4	7	14	44	1.8	0.37, 8.39
Chewing on pens or pencils	4	7	15	45	1.7	0.44, 6.68
Eating cookies made by index patients' family	3	8	13	47	1.4	0.31, 5.89
Care of infants: physical therapy	8	3	41	19	1.2	0.29, 5.23
Smoking	3	8	13	47	1.4	0.31, 5.89
Care of infants: dressing changes	9	2	48	12	1.3	0.21, 5.97
Eating cafeteria food on the BC	10	1	56	4	0.7	0.07, 7.12
Biting fingernails	1	10	16	44	0.3	0.04, 2.42

Note. All of the control subjects did not respond to each questionnaire item, so the total number of health care workers who did not become ill does not equal 60 for all items.
[a]All variables have a *P* value of <.10 or were suggested by previous studies as potentially important.
[b]95% confidence interval about the odds ratio was calculated with test-based Mantel-Haenszel estimates about the odds ratio.
[c]Logit estimators of the 95% confidence interval use a correction of 0.5 to every cell of those tables that contain a zero.

tively, during the next 2 months. No other clustering of hepatitis A infections was noted at restaurants or other facilities in the county of origin during the period of the outbreak. Anti-HAV serology was obtained from the two donors reporting symptomatic illness coincident with the blood donations.

Characteristics of the Study Samples

Ninety-two percent (n = 132) of the questionnaires from potentially eligible controls (n = 154) were returned; all case subjects returned the questionnaire. Controls were required to be both serosusceptible (negative for total anti-HAV antibody) and to have returned the questionnaire (n = 91, Figure 3). The control group was further refined by limiting the group to the same job classifications (i.e., those with maximal patient exposure) as those of the health-care-worker case subjects (e.g., nurses, nursing assistants, nursing students, and ward clerks; n = 60). The reported rates of hand-washing after patient care, hand-washing after diaper changing, and wearing gloves when contact was anticipated with blood and body fluids or secretions were similar for both groups. After patient care, 82% of the case patients and 75% of the controls reported that they washed their hands routinely (relative risk [RR] = 1.09, 95% confidence interval [95% CI] = 0.77, 1.55). After diaper changing, 91% of the case patients and 100% of the controls reported always washing their hands (RR = 0.95, 95% CI = 0.85, 1.06). Similarly, 82% of the case and 63% of the control subjects reported consistent use of gloves when contact with blood or body fluids was anticipated (RR = 1.29, 95% CI = 0.85, 1.98).

Nursing assignments. The infection rates for nurses assigned to either patient were the highest during the exposure week of January 2 through January 8, 1990, just before the onset of symptoms in the father. During that week, the infection rates among nurses assigned to two or more shifts with the infant were higher than those for nurses assigned to a single shift (4 of 5 [80%] vs 1 of 6 [17%], respectively). Similarly, infection rates were higher for nurses assigned to two or more shifts with the infant's father than for nurses assigned to a single shift (3 of 3 [100%] vs 1 of 13 [8%], respectively). The cumulative incidence risk ratio was elevated for nurses caring for either th infant (RR = 14.6, 95% CI = 3.4, 63.2) or his father (RR = 10.6, 95% CI = 2.2, 50.2) during that same week. The only two nurses assigned to care for both patients during the same week also became ill.

Risk factor assessment. The univariate analysis (Table 1) identified the following significant risk factors for hepatitis A infection: eating on the ward (odds ratio [OR] = 14.2, 95% CI = 2.5, 80.5), bringing snack foods to share with others (OR = 8.8, 95%

CI = 2.4, 31.3), and providing hydrotherapy treatments (OR = 5.9, 95% CI = 1.3, 26.1). Of 12 different types of patient care given to adults or infants, none appeared to predispose workers to hepatitis A infection. No other risk factors (e.g., smoking, chewing on pens or pencils, eating specific snack foods at work, eating out with coworkers) were statistically significant risk factors. After correction for confounding variables with a stepwise logistic regression analysis, the single important risk factor for the development of infection was frequent eating on the ward (OR = 14.2, $P = .0029$). No additional variables met the criteria for retention in the model ($P < .05$) or improved the single variable model.

Discussion

Health care workers caring for thermally injured patients are potentially exposed to a variety of blood-borne pathogens daily through the open burn wounds that must be debrided with hydrotherapy and frequent dressing changes. In our burn treatment center, both case and control subjects reported a high level of prior compliance with routine handwashing, glove use, and other barrier forms of universal precautions. Nevertheless, an important outbreak of hepatitis A occurred in a burn treatment center involving 11 health care workers and 1 patient with a secondary case. Once the epidemic was recognized, reemphasis of good hygienic and isolation practices and the administration of immunoglobulin apparently prevented other secondary cases. Although the relative contributions of each of these measures in terminating the outbreak cannot be assessed in the current study, we would recommend the use of a similar approach for control of a nosocomial outbreak.

We were unable to determine the source of hepatitis A infection in the two index patients. The usual incubation period of 10–50 days (mean = 1 month) is consistent with either nosocomial or community-acquired disease.[18] The elevated cumulative incidence ratios among nurses exposed to either case in the week before onset of symptoms in the adult index patient suggest that both index patients were most infectious during that period, which corresponds to the time of greatest fecal shedding of hepatitis A virus. We also have epidemiologic evidence of an exposure dose–response relationship: the infection rates were higher for nurses assigned to more than one shift than for nurses assigned to only one shift with either patient and highest among nurses assigned to care for both patients. However, the infant son may have been infected before his arrival at the hospital, explaining the exposure to and timing of the disease in his father. Infants usually remain asymptomatic, liver enzymes may not be elevated, and secretion of virus in the stool may continue for weeks.[8]

Similar exposure dose–response relationships have been reported in the literature. In one multistate outbreak of 55 cases, the 16% infection rate among susceptible nurses was four times higher than that among physicians with considerably less exposure to case patients.[4] Moreover, nurses working 12-hour shifts were significantly more likely to become infected than those working 8-hour shifts. In another epidemic, nurses assigned to two or more shifts with an infected infant with an ileostomy had an infection rate 4.6 times higher than those assigned to a single shift.[5]

Because the index patients did not have direct contact with each other until after the onset of illness in the father, a nosocomial source for their infections appears unlikely. Nevertheless, a possible nosocomial source would be a contaminated blood product given to both patients. Transfusion-associated hepatitis in neonates has been recognized as the source of several nosocomial outbreaks involving health care workers.[3-6] However, in our center, none of the donors gave blood to both patients. Moreover, of the 33 donors contributing blood to either patient, only 2 reported feeling ill near the time of their donation. Hepatitis A serologic tests from both of the latter donors were negative.

The outbreak occurred in the setting of a national increase in the incidence of hepatitis A in the United States.[19] At the time of the outbreak, the incidence of community-acquired hepatitis A in the state of Iowa was fivefold higher than that in the previous year, with one fourth of the cases occurring in the same county of origin as the index cases.

Up to one third of community-acquired cases of hepatitis A have been linked to day-care centers.[20-22] However, in our study, none of the children tested or family members of the babysitter from the small day-care home that had previously cared for the index infant were seropositive. Nevertheless, one of the six children cared for in the center could not be contacted for testing. Similarly, no apparent common source of exposure could be identified for the index family in the 2 months before admission.

A case–control study using seronegative, susceptible health care workers as controls convincingly demonstrated that frequent eating on the ward was the single most important risk factor for development of hepatitis A infection. Importantly, previous investigations of nosocomial outbreaks of hepatitis A have typically failed to implicate a particular mode of transmission. The finding that hepatitis A infection is clearly associated with eating on the hospital ward is not only biologically plausible, but also is entirely consistent with the acknowledged fecal-oral route of transmission of hepatitis A infections.

Our data indicating nonroutine handwashing by approximately 25% of health care workers and nonroutine use of gloves by 37% of health care workers are self-reported, retrospective, and conservative estimates of compliance with standard hygienic procedures. These results support the previous findings of Rosenblum et al.,[8] who found a significantly increased risk of infection during an outbreak in a neonatal intensive-care unit among health care workers who did not wear gloves when taping an intravenous line.

We speculate that hygiene was suboptimal in the burn center before the outbreak and that hand contamination probably occurred. Hand contamination may have occurred after providing hydrotherapy (9 of 11 cases) or after other patient care activities. Subsequently, nosocomial infection likely occurred either through eating snacks or sharing food on the ward. The strategic placement of sinks at the entrance to the center may have resulted in improved hand-washing on leaving the burn treatment center and explain the lack of association of illness with eating in the hospital cafeteria. A food-related outbreak was also unlikely because there was geographic clustering of the cases on a single patient unit, serologic tests for hepatitis A among dietary workers were negative, and there was no supportive evidence in the case–control study. Importantly, none of the snack foods available on the center or the specific food items at the potluck dinner were associated with illness. However, we are unable to exclude absolutely the possibility that food contamination rather than, or in addition to, contamination of health care workers' hands was the apparent mode of transmission.

Previously reported outbreaks have been linked to patients with vomiting, diarrhea, or fecal incontinence.[9-14] An out-

break of hepatitis A in a pediatric intensive-care unit in 1981 involving 10 secondary cases suggested that food was a potentially important risk factor.[9] The apparent index patient in that outbreak had been incontinent of feces for several days before his death. His family had frequently brought in food that they shared with the boy and members of the staff. Sharing food with patients or their families, drinking coffee at work, sharing cigarettes, and eating in the nurses' office increased the likelihood of infection, although none of the variables reached statistical significance.[9] Moreover, in another study, case patients were almost three times more likely to smoke than were controls (36% vs 13%), suggesting the importance of the fecal-oral route of transmission.[5] Similarly, Rosenblum and colleagues[8] reported that drinking beverages in the intensive-care unit was a significant risk factor for infection.

Recent data demonstrated that hepatitis A virus survives well on the fingerpads, despite drying, for 4 hours.[23] Additionally, the virus was transferred effectively between fingerpads and from fingerpads to clean surfaces despite prolonged drying. After suspensions of the hepatitis A virus were dried for 20 minutes, an inoculum of the virus was transferred from an inanimate surface to the fingerpads. Both pressure and friction significantly increased the transfer of hepatitis A virus. The results of this experimental study support the importance of human hands in the direct spread of hepatitis A observed in the current outbreak.

The diagnosis of acute hepatitis A is usually confirmed easily by the presence of a positive IgM anti-HAV serologic test, which is typically positive very early in cases of acute infection.[18,24] Four of our patients developed nausea, vomiting, and elevated alanine aminotransferase levels but were initially seronegative. Each of these case patients, however, developed IgM anti-HAV antibody over the next 5 to 7 days. Our findings confirm those of Zachoval and colleagues,[25] who recently reported four patients with early acute hepatitis A infection who were initially seronegative for IgM anti-HAV antibody. Therefore, patients suspected of having early hepatitis A infection but who have a negative IgM anti-HAV test should have the test repeated several days later.[25]

Our results confirm the empiric observations of Drusin and colleagues[9] and Reed et al.[10] and are consistent with previous guidelines[26] suggesting that eating on the hospital ward when hygiene is suboptimal predisposes health care workers and patients to hepatitis A. Moreover, the combination of a low level of population immunity and an increase in the incidence of hepatitis A infection in the United States suggests that other hospitals may soon experience similar clusters of infection if health care workers continue to eat on the hospital ward. □

Hepatitis B Control in China: Knowledge and Practices among Village Doctors

ABSTRACT

Objectives. To guide development of a hepatitis B control program in China, we investigated village doctors' sterilization practices, injection use, vaccination levels, and knowledge and counseling skills.

Methods. The head doctor from each village health station in a rural county (n = 260) completed a self-administered questionnaire.

Results. Of the respondents, 94.2% reported adequate sterilization of needles; however, inadequate sterilization of syringes and acupuncture needles was common. Injections were found to be frequent and profitable. Of head doctors, 16.2% reported that most infants in their villages are vaccinated against hepatitis B. There was very high knowledge of modes of hepatitis B transmission, but it was not used to formulate advice for a hypothetical carrier. Knowledge of the consequences, prevalence, and use of condoms to prevent sexual transmission was lower.

Conclusions. The sterilization of acupuncture needles, reuse of syringes, and frequent injections are practices that may transmit the hepatitis B virus. Research into issues of vaccine acceptance is needed to expand immunization. A review of treatment practices and better training in counseling for village doctors is suggested. Introduction

In the People's Republic of China, approximately 10% of the population is chronically infected with the hepatitis B virus (HBV),[1] with rates as high as 15% in the southern coastal provinces such as Fujian.[2] Approximately 25% of individuals who are chronic carriers of HBV will die of cirrhosis or primary hepatocellular carcinoma.[3] In Fujian, liver cancer accounts for 22.36% of cancer mortality in males and 13.75% in females.[4] HBV is transmitted primarily percutaneously through blood, blood products, and semen. Perinatal transmission has been estimated to account for 30% to 50% of HBV carriage in China.[5] The spread of HBV through medical practices such as injections[6] and acupuncture remains an important concern, as does intrafamilial transmission. Because the likelihood of becoming a chronic carrier decreases as age at infection increases,[7] prevention of infection in infancy is the top priority. The hepatitis B vaccine is both safe and effective,[8–10] and universal immunization of infants at birth is the most cost-effective strategy for China.[11] Although immunization at birth is routine in many city hospitals, efforts in rural areas are hampered by the cost of the vaccine and difficulties in transportation, storage, and training.

Our survey focused on village doctors because of the important role they play in the control of iatrogenesis and in the implementation of vaccination and health education programs at the village level. Like the "barefoot doctors" who preceded them, the village doctors are first-line health care providers in rural areas. However, in recent years there has been an effort to upgrade their training, and in many areas where the cooperative medical care system has been dismantled, they work on a fee-for-service basis.[12] Our survey investigated village doctors' sterilization practices, frequency of injection use, current vaccination practices, and knowledge of hepatitis B and counseling skills.

Methods

Setting

Minhou is a rural, middle-income county surrounding Fuzhou, the capital city of Fujian Province. The county is composed of 294 villages divided into 15 townships. Most villages no longer have a fully cooperative medical care system, and simple fee-for-service is common. A 1990 survey by the Minhou Epidemic Prevention Station of 1862 children aged 4 through 6 years found 14.9% to be HBsAg positive (i.e., carriers of the hepatitis B surface antigen). At present there are no data available to establish the carrier rate among adults. The Fujian Epidemic Prevention Station reports the prevalence of HBsAg positivity in the province as a whole to be 14.93%. In Minhou, as in most other rural areas in the province, hepatitis B has not been targeted as a priority health

problem. Consequently our findings are probably generalizable to many similar rural areas.

Procedure

Of the 294 villages in Minhou, 260 have village health stations. The head doctor from each health station completed a confidential, self-administered questionnaire that included items on demographics; sterilization, treatment, and counseling practices; and knowledge of HBV transmission, symptoms, and prevalence. The 100% response rate is not unusual in China, where, under the authoritarian system of government, a request for participation is generally viewed as a requirement. One hundred eighty-two doctors completed the questionnaire in one of the 15 township centers during a regular meeting and were reimbursed for transportation and a meal. Seventy-eight doctors completed the questionnaire when a data collector came to their village.

Subjects

Most of the subjects (81.2%) were male and the mean age was 37 years. Most were middle school (56.9%) or high school (38.5%) graduates. The amount of medical training varied: 1 year, 23%; 1 to 2 years, 40%; 2 to 3 years, 19%; more than 3 years, 19%. Eighty percent of the doctors had the "village doctor certificate," which indicates that they have met the national standard for medical knowledge at this level. The mean number of years in practice was 16.2. About one third (34.2%) of the doctors reported that their health station was classified as "first-rate," indicating that it has three rooms, a certified village doctor, a female practitioner, all designated essential drugs, and all national regulations for rural health care.

Results

Sterilization Practices

Most of the doctors (98.1%) reported never using the same needle to inject two patients without sterilizing it. However, only 23.5% reported that they were always able to adhere to the national guideline of "one person, one needle and syringe," probably because syringes are often separated from the needle and reused without sterilization. With respect to methods of sterilization, 59.6% reported sterilizing needles with a pressure cooker and 38.5% reported boiling needles. Eleven doctors (4.2%) reported boiling needles for an insufficient length of time (5–15 minutes). Only one doctor reported using a chemical method of sterilization and four (1.5%) reported washing needles with boiled water. Thus, of 260 health stations, the head doctor at 15 (5.8%) reported an inadequate method of sterilization.

Sterilization of acupuncture needles poses a much greater problem, because they are damaged when brought to high temperatures. National guidelines call for sterilization with glutaraldehyde. Yet of the 76% of doctors who reported that acupuncture is practiced "sometimes" or "often" at their health station, 91.4% sterilized needles with alcohol, which does not reliably destroy HBV. Chemical or other methods of sterilization that do not conform to the national guidelines were reported by 8.6% of the doctors.

Injection Frequency

Subjects were presented with the symptoms and diagnoses for seven hypothetical cases, all of which could be treated with oral medication. The seven cases were upper respiratory infection in a 1-year-old (with fever, congestion, and light cough); mumps in a 2-year-old; nutritional microcytic anemia in a 4-year-old; thiamine deficiency in a middle-aged farmer; early pregnancy in a married woman of unspecified age; echovirus-caused diarrhea in a 2-year-old; and acute conjunctivitis in a patient of unspecified age. The respondents were asked to list the medications and methods of delivery they would use.

For all seven cases together, a mean of 4.19 injections would have been administered (SD = 2.00). Table 1 presents the percentage of respondents who would administer one or more medications by injection and the percentage of all medications used that the respondents would administer by injection. There were no statistically significant bivariate associations between the total number of injections administered for all seven cases and various characteristics of the respondent

and the health station. Table 2 presents the mean number of injections that would be given for the upper and lower (or yes/no) level of each variable.

The doctors were also asked about patients' preferences for methods of drug delivery and the profitability of prescribing oral medications vs giving injections. Most (89.2%) said that patients prefer oral medications. However, when asked what type of drug delivery parents prefer for infants, the reported preferences were oral medications, 28.5%; injections, 21.5%; and both, 49.2%. These responses were grouped into two categories: oral vs injections or both. In three of the four hypothetical conditions dealing with small children, a greater percentage of doctors who felt parents preferred injections or both would administer injections than would doctors who felt parents preferred oral medications: 1-year-old with respiratory infection (68% vs 49%), 4-year-old with anemia (56% vs 47%) and 2-year-old with echovirus-caused diarrhea (46% vs 37%). This difference was statistically significant only in the first case ($\chi^2 = 8.5, P << .01$). With respect to profitability, 91.9% of the subjects reported that it was more profitable for them to administer the same medication by injection than orally.

Vaccination and HBV Testing

Only 11.2% of the doctors reported that most pregnant women in their village are tested for HBV; 60.8% reported that none are tested. The most common reason for women's not receiving the test, given by 58.5% of the doctors, was that the test cannot be performed by the township hospital (58.5%); 34.6% reported that women do not want to be tested, and only 3.1% reported that doctors do not recommend the test.

Vaccination of infants was slightly more common than prenatal testing: 16.2% of the doctors reported that most infants are vaccinated and 48.1% reported that almost none are vaccinated. Of the doctors from first-rate health stations, 64% reported that "most" or "a few" infants are vaccinated, compared with 46% of those from stations that are not first-rate ($\chi^2 = 8.05, P = .02$). The reasons given for nonimmunization were unavailability of the vaccine (68.1%) and cost (24.6%).

Knowledge of HBV

Knowledge of modes of HBV transmission was high. More than 90% knew that HBV could be transmitted by needles, acupuncture, blood products, dental equipment, shared toothbrushes, mouth-to-mouth feeding of infants, and other contacts within the family. Similarly, 90% or more knew that HBV could not be contracted from being out in the sun or catching a chill. Although 87.3% knew that HBV could be sexually transmitted, only 38.5% believed that condoms would prevent transmission. Incorrect responses appeared to be related to confusion with the fecal-oral transmission of hepatitis A. Sixty to sixty-three percent believed that not washing hands after going to the bathroom and eating off dirty dishes could transmit HBV; 36.2% believed that hepatitis B could be contracted by eating spoiled food. Knowledge of the consequences and prevalence of HBV infection was not high: 43.1% did not know that HBV causes liver cancer, and 23.5% believed that hepatitis B is easily cured. Only 24.2% correctly identified the percentage of carriers as 10% to 30%; 41.2% underestimated the rate at 1% to 10%, and 32.3% overestimated the rate at more than 50%.

Table 2 presents the bivariate relationships between total knowledge scores (the sum of 24 true/false items) and various respondent characteristics. Although having more education, having more years in practice, having the village doctor certificate, and being older were all associated with higher knowledge scores, the actual differences in scores were very small. Together these four variables explained only 11.0% of the variation in the total knowledge score in a multiple linear regression model ($F = 7.85, P << .01$), and the village doctor certificate alone accounted for 6.2%.

To determine how knowledge of hepatitis B might be put into practice, we asked the respondents to write down the advice they would give to an HBV carrier. Although our intent was to elicit advice to an asymptomatic carrier, the responses suggest that the question was interpreted to refer to a person with acute HBV infection. Table 3 presents the responses given by 5% or more of the respondents, divided into two categories: those that relate to preventing the transmission of HBV to others and those that relate to improving the health of the carrier/patient. Because of the possible misinterpretation, we restrict our comments to the former subset of responses.

Although the true/false items revealed high knowledge of the modes of transmission of HBV, this knowledge was not employed when formulating advice. The most effective measure, vaccination, was mentioned by only 8.5% of the respondents. Furthermore, only nine doctors (3.5%) would caution a carrier against donating blood. One said that women carriers should not become pregnant, one mentioned use of condoms, and four cautioned against sexual activity. The high percentage of respondents (36.2%) who suggested sterilizing excrement again suggests confusion of hepatitis B with hepatitis A.

TABLE 3—Advice Given to a Hypothetical Hepatitis B Carrier/Patient by 5% or More of Respondents

Advice	%
To prevent transmission	
Separate/do not share toothbrush, eating utensils	84.6
Sterilize, use chlorine bleach for excrement	36.2
Do not go to public places (bathroom, theater, restaurant)	21.9
Vaccinate against hepatitis B virus	8.5
Wash hands after going to the bathroom	5.0
To improve health of carrier/patient	
See doctor/have blood tests/get proper treatment	47.7
Rest/avoid overworking	33.8
Pay attention to nutrition	25.8
Do not eat fatty foods	6.9
Abstain from alcohol or tobacco	6.9
Exercise	5.8

Discussion

Our self-report data indicate widespread inadequacy of sterilization of acupuncture needles and syringes, but not hypodermic needles. However, because acupuncture is rarely practiced on young children, it may not contribute greatly to the rate of chronic HBV infection. Similarly, the contribution of syringe reuse to total HBV carriage is unknown. However, studies demonstrating the resilience of HBV and the facility with which contamination can occur[13,14] suggest that a much more thorough, observational study of medical practices in rural areas is needed. Needles, for example, can easily be contaminated after sterilization.

Our findings of frequent injection use corroborate previous observations in both China[15,16] and other developing countries.[17] The use of injections was not associated with specific characteristics of the doctor or health station; however, doctors were more likely to treat children with injections if they believed the parents

preferred injections. Efforts to reduce the use of injections must focus simultaneously on patients' expectations and providers' practices to address the complex interaction that shapes treatment practices.

Reported levels of hepatitis B vaccination were higher than expected: 16.2% of the village doctors reported that most infants are vaccinated. China is currently in the process of expanding production of the hepatitis B vaccine to increase availability and reduce costs. If these efforts are successful, it is likely that many more parents will be willing to purchase the vaccine for their newborns. Further research into the methods of vaccine delivery and parental knowledge and attitudes is needed for the expansion of immunization coverage.

Doctors at the village level appear to have a good understanding of the transmission of hepatitis B, although there is some confusion with hepatitis A. Not surprisingly, doctors who have not obtained the village doctor certificate appear to have the greatest need for further education about hepatitis B. Otherwise, we did not find any other predictors of practical significance. The lack of useful advice given to a hypothetical carrier/patient suggests that information on HBV has been memorized but not put into practice.

Village doctors are trained through study and practicum, primarily at the township level. Although they participate in regular in-service training, there is little supervision of their activities in their own villages. Our findings suggest that although this system has been reasonably successful with respect to knowledge of hepatitis B, it has not adequately addressed the area of practice. Further training in counseling of HBV carriers and a review of treatment practices should be conducted in conjunction with hepatitis B control efforts. □

Patient-to-Patient Transmission of Hepatitis B in a Dermatology Practice

ABSTRACT

Objective. The purpose of the study was to investigate infection with hepatitis B virus (HBV) and human immunodeficiency virus (HIV) among patients in a dermatology practice.

Methods. Historical cohort, matched case–control, and cross-sectional survey methods were used.

Results. The age-specific incidence of reported HBV infection in the practice from 1985 through 1991 was more than 12 times the expected rate. The dermatologist was not an HBV carrier. He practiced neither universal precautions nor sterile surgical technique. Seroprevalence of markers for HBV infection was highest (36.8%) among patients who had had surgery on the same day that HBV was apparently acquired by an index case; seroprevalence was near the expected background level for patients not exposed to index cases. Of HBV-infected patients with known dates of onset, 72% had had surgery during their incubation periods. All of 30 HBV antigen specimens tested were of the same subtype. None of the patients tested, including 74 patients exposed to surgery on the same day as a patient with acquired immunodeficiency syndrome, had evidence of HIV infection.

Conclusions. HBV, but not HIV, was transmitted from patient to patient by the dermatologist's failure to apply either universal precautions or sterile surgical technique. (*Am J Public Health.* 1993;83:1689–1693)

Introduction

Concerns regarding the risk of acquiring hepatitis B virus (HBV) and other blood-borne infections during medical and dental procedures have increased owing to the epidemic of acquired immune deficiency syndrome (AIDS) and apparent transmission of the human immunodeficiency virus (HIV) in a dental practice.[1] Transmission of HBV in health care settings is much more common than transmission of HIV. Outbreaks of HBV infection have resulted from transmission of the virus from infected health care workers to their patients,[2–4] and patient-to-patient transmission has been described in nosocomial outbreaks[5–7] and in alternative-care settings, such as acupuncture clinics.[8–10] In this report, we describe a large outbreak of HBV infection that was the first identified as resulting from patient-to-patient transmission in a conventional outpatient medical practice.

In September 1991, public health officials in Lee County, Florida, recognized that eight patients with acute HBV infection reported since 1985 had visited a Fort Myers dermatologist prior to onset of their disease. The dermatologist had no history of acute hepatitis or hepatitis B immunization. In 1987, he was found to be hepatitis B surface antigen (HBsAg) negative and hepatitis B surface antibody (HBsAb) positive, indicating that he was not a carrier but had been previously exposed to HBV. Patient records indicated that he had seen more than 10 000 patients since 1985, most of whom were White and older than 54 years of age.

Although the investigation was initiated by reports of HBV-infected patients, there was concern that HIV may have been transmitted as well.

Methods

Practice Evaluation

The dermatologist was interviewed regarding office practices and procedures, and he was instructed regarding universal precautions to control the spread of HBV and other blood-borne disease.[11] He was subsequently observed with 16 consecutive patients by one of the authors (W. G. H.) to determine whether universal precautions were being followed. Office autoclaves were tested for proper timing, temperature, and pressure.

Incidence Study

Only records for active patients and patients whose charts had been open in 1985 or later were available for review. Chart review identified all of the dermatologist's patients who had been reported to the Lee County Public Health Unit with acute HBV infection from January 1985 through September 1991, including those for whom exposure to the dermatologist was not mentioned in the original case reports. The findings were used to calculate the proportion of all reported cases of acute HBV infection who were patients of

the dermatologist and to estimate the incidence of reported cases in his practice.

Case–Control Study

Early in the course of the investigation, we conducted a case–control study to test the hypothesis that HBV-infected patients were more likely than other patients to have had a surgical procedure during the incubation period of the disease (45 to 180 days before onset of symptoms). Case patients were persons reported with acute HBV infection with a known date of onset for whom treatment records were available from the dermatologist. Three randomly selected control patients with available treatment records were matched with each of 20 case patients by age (± 10 years) and year of visit—that is, controls visited the dermatologist at least once during the same year that the corresponding cases acquired their infections. The control patients were randomly selected from among patients of the dermatologist who were not reported with hepatitis B.

Relative risk was estimated by the matched odds ratio (OR) with a 95% confidence interval (CI).[12] The probability (*P*) that the observed matched odds ratio might have occurred by chance was obtained by stratified Mantel-Haenszel analysis, with each stratum consisting of one case and three matched controls.[13]

Cross-Sectional Study of HBV Seroprevalence

On the basis of the results of the case–control study, we defined patients at high risk of exposure as those who had had surgery within 1 day of surgery on HBV-infected patients during their incubation periods and those who had had surgery on the day of or the day after surgery on HBV-infected patients subsequent to their incubation periods. Nearly all of the surgical procedures consisted of excisional biopsies, but no appointment records were available for years prior to 1991; therefore, most of the high-risk patients were identified through pathology reports, which indicated the date on which a surgical specimen was submitted. High-risk patients were notified individually by mail of the possibility that they had been exposed to HBV and "other blood-borne disease" and were urged to appear for testing. In addition, media publicity attracted a large number of patients for testing who had not been identified as high risk. All patients who appeared for testing were offered tests for HBsAb, HBsAg, and antibodies to HIV.

Testing was provided free of charge from November 7 to December 18, 1991. Sera were screened for HBsAg and HBsAb with standard enzyme immunoassay reagents (Abbott Laboratories). Positive HBsAg results were confirmed by virus neutralization. In addition, the HBsAg in specimens from 30 patients—selected because they had known dates of onset or documented exposures to other infected patients—were subtyped, using monoclonal antibodies with restricted specificity in an enzyme immunoassay.[14] Screening for antibodies to HIV was also performed by enzyme immunoassay (Genetic Systems).

Informed consent was obtained for all testing, and pre- and posttest counseling was given to all patients who consented to be tested for HIV. All patients with positive test results were interviewed regarding hepatitis B vaccination, compatible clinical illness, onset dates, and possible risk factors, such as blood transfusions, injection drug use, male homosexuality, and contact with an infected family member or sexual partner.

The test results from patients without a history of hepatitis B vaccination were used to calculate prevalence of serum markers for infection for several categories of exposure. Only patients with a single exposure in a single given category were included in these calculations, with one exception—all unvaccinated patients not identified as being at high risk of infection were included in a comparison group, regardless of the number of times they were seen in the practice. Standard methods based on the binomial probability distribution were used to calculate confidence intervals for prevalence and to test the significance of differences in prevalence ratios between categories.[15]

A number of patients were tested by private health care professionals. Because not all results were reported to us, patients tested privately who did report their positive results to us were included in case counts but were not included in the calculation of prevalence ratios.

Cross-Sectional Study of HIV Seroprevalence

Local AIDS surveillance staff searched patient files in the dermatology practice to find records for patients who had been reported with AIDS and to abstract their treatment histories. Patients who had had surgery on the day of or the day after surgery on a patient with AIDS were identified as being at high risk of exposure to HIV. These patients were then notified and tested in exactly the same manner described above.

Results

Reported Incidence

A total of 30 of the dermatologist's patients were reported with acute HBV infection from 1985 through 1991. Twenty-three were older than 54 years at the time of diagnosis, representing 52% (23/44) of all HBV-infected patients reported from Lee County in that age group. The estimated incidence of reported HBV-infected patients older than 54 years in the dermatology practice was 71.8 per 100 000 person-years, more than 12 times the rate of 5.9 observed for the same age group in the county as a whole during the same period.

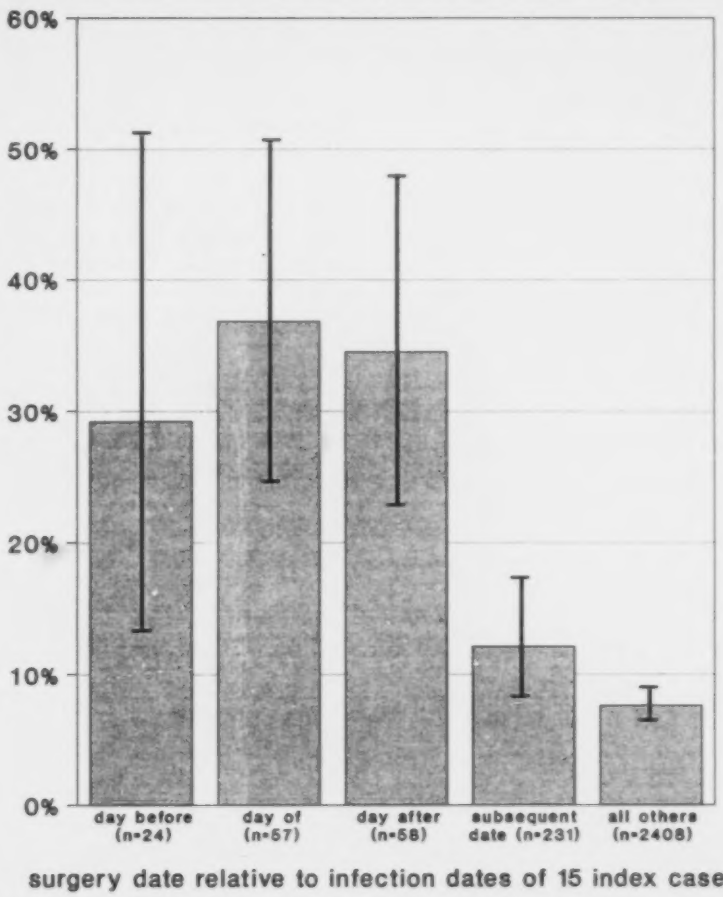
Case–Control Study

Eighty percent (16/20) of the case patients and 40% (24/60) of the matched control patients had had surgery during the case patients' incubation periods (matched OR = 9.00; 95% CI = 1.82, 44.45; $P = .003$). Subsequently, six of the control patients appeared for screening; two were identified as having been infected with HBV. Neither had a known date of onset, and both had had surgery in the practice during the incubation periods of their matched case patients. When these two control patients were deleted from the analysis, the matched OR was 9.33 (95% CI = 1.93, 45.04; $P = .002$).

Cross-Sectional Study of HBV Seroprevalence

Surgery dates of 22 HBV-infected patients (index case patients) were used to identify a total of 736 patients as being at high risk of infection. Four hundred (54%) of these high-risk patients, excluding those who had received hepatitis B vaccine, were tested for HBsAb and HBsAg. Twenty percent (80) tested positive by one test or the other, compared with 7.6% (183) of 2408 other unvaccinated patients who appeared for testing as a result of media publicity or because they were identified as high risk only for infection with HIV (risk ratio = 2.63; 95% CI = 2.07, 3.35; $P << .01$).

The seroprevalence results were further divided into five categories of exposure, shown in Figure 1. Seroprevalence of markers of HBV infection was highest, at 36.8% (95% CI = 24.7, 50.7), among those patients who had had surgery on the same day that an index case patient ap-



Note. Infection dates of index cases are dates of surgery during the case patients' incubation periods. Except for the "all others" category, only patients with a single surgical exposure in a single given category were included in the prevalence calculations. Some patients in the "all others" category may have been exposed to HBV-infected patients in the practice who had not been identified at the time of screening.

FIGURE 1—Prevalence of serum markers for HBV in five risk groups.

parently acquired his or her infection. Seroprevalence was also relatively high among those who had had surgery the day before or the day after an index case patient's apparent infection date. Having a surgical procedure on days when index case patients had subsequent surgical procedures was also associated with a prevalence significantly greater than that observed for patients not in a high risk category (12.1% vs 7.6%, $\chi^2 = 5.86$, $P = .02$).

Exposure Histories

A total of 305 unvaccinated patients in the dermatology practice, including index case patients, had serological evidence of infection with HBV. Of these, 69 had known dates of onset and patient records available for review. These patients had an average age at onset of 67 years (range: 29–91); 38 were men and 31 were women. Patient records documented surgery by the dermatologist during the incubation periods for 50 (72%) of the HBV-infected patients with known dates of onset, including 2 who eventually died of the disease. The mean incubation period was 126 days (range: 58–168 days).

Of the 19 HBV-infected patients with known dates on onset and available treatment records who had no record of surgery during their incubation periods, 2 were spouses of patients with HBV infection who had had surgery in the practice during their incubation periods, 1 was a homosexual man, and 3 had been seen during their incubation periods but there was no record of a surgical procedure. The remaining 13 patients had no known risk factors for HBV infection.

None of the HBV-infected patients with documented surgery in the practice during their incubation periods had any other risk factors for HBV infection.

HBsAg Subtyping

The epidemic curve (Figure 2) shows 70 of the 72 HBV-infected patients with known dates of onset. The 2 patients not shown were both chronic carriers of HBV, one with onset in 1945 and the other with onset in 1965. Subtyping of HBsAg from the patient with onset in 1945, along with 29 others, showed that all were subtype *adw2*.

HIV Exposures and Seroprevalence

The practice included 22 patients with AIDS; all had died by the time of the investigation. Two had no identified risk factors. Each of these 2 had had only one surgery in the practice, at 5 and 15 months prior to their deaths. A total of 11 surgical procedures had been performed on 9 of the patients with AIDS in the practice, but none on a day that HBV was apparently transmitted. One hundred eighty-nine patients had had surgery on the same day as surgery on an AIDS patient or on the day after, and 74 of these, including 2 who were exposed twice, were tested for antibodies to HIV. Results for all of the 74 exposed patients and all of the other 2621 patients tested were negative.

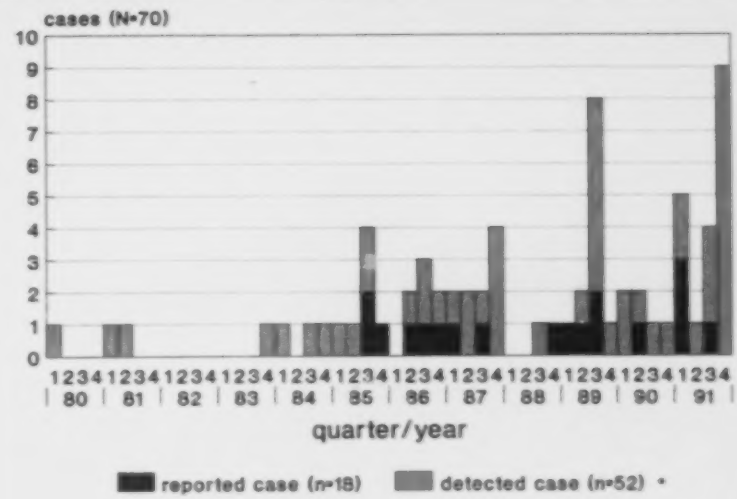
Possible Vehicles for HBV Transmission

Possible vehicles for HBV transmission between patients included the dermatologist's hands, injectable solutions in multiple-use vials, electrocautery tips, and liquid nitrogen.

The dermatologist's hands were often contaminated with blood, as he routinely operated without gloves and failed to wash his hands after every patient.

Injectable anesthetic solution (1% lidocaine without epinephrine) in multiple-use 50-cc vials may have been contaminated. Only one 5-cc syringe was used per patient. If additional solution was required, the same syringe was refilled through a needle that remained in the vial and was common to all other patients seen that day.

Electrocautery tips were neither changed nor cleaned between patients, and cotton-tipped liquid nitrogen applicators were occasionally returned to the res-



* Patients tested November 7 - December 18, 1991.

Note. Reported cases were investigated by the county public health unit at the time of diagnosis. Detected cases were identified by serologic screening for HBsAb and HBsAg, with onset dates determined by patient history of jaundice or acute illness diagnosed as hepatitis B.

FIGURE 2—Onset dates for 70 HBV-infected patients in a dermatology practice, 1980 through 1991.

ervoir after use (although liquid nitrogen was not used in the surgical procedures examined by our investigation). We found no other problems with office sterilization equipment or procedures for cleaning and sterilizing instruments.

Discussion

Investigation of this outbreak was complicated by several factors. The infections occurred over a long period of time among a large number of people. Many infections were asymptomatic, and reporting of symptomatic infections was incomplete. Nevertheless, a strong argument can be made that patient-to-patient transmission of HBV occurred with disturbing frequency. The observation that HIV was not also transmitted in this setting is consistent with earlier estimates of the relative infectivity of the two viruses[16–18] and further emphasizes the importance of HBV as a blood-borne pathogen in the health care setting.

The incidence calculations confirmed the existence of an outbreak. The number of person-years of exposure to the practice was necessarily a rough estimate for calculation of a rate of infection. However, any error introduced was unlikely to account for the 12-fold difference between the estimated rate of reported HBV infection in the practice and that observed for the county as a whole.

The hypothesis that infection was transmitted via surgical procedures was based on biologic plausibility and the dermatologist's description of his surgical technique. It is possible that some control patients in the case–control study, in addition to the two we identified, may have been infected with HBV, but such misclassification would only have reduced our estimate of the matched odds ratio. The level of risk indicated by the matched odds ratio, therefore, represents a minimum estimate.

The results of the case–control study suggested high-risk subsets of patients to actively screen for evidence of infection, both with HBV and with HIV, and the validity of this classification was confirmed by the test results. Seroprevalence of markers for HBV infection was significantly elevated among high-risk patients in a pattern predicted by our hypothesis that patient-to-patient transmission occurred during surgical procedures.

The elevated prevalence of markers of HBV among patients who had had surgery the day before or the day after apparent infection of an index case patient is consistent with transmission by a vehicle, such as contaminated solutions for injection, that could have been used on successive days. Multiple-use vials for injection were identified as the likely vehicle of infection with HBV in a previous outbreak, and the potential certainly existed for contamination of the 50-cc vials of local anesthetic solution as they were used in this dermatology practice.[6]

Declining seroprevalence among patients exposed to days of subsequent surgery on index case patients probably reflects waning antigenemia. And seroprevalence in the low-risk patients with no known exposure to an index case patient (7.6%) was close to the 7% found in Whites older than 54 years in a representative sample of the general US population.[19]

The time of introduction of HBV into the practice is unknown. Two carriers of HBV with long histories of infection were identified in the practice, and the dermatologist himself may have been a source at some time prior to 1987. However, there is good evidence that HBV transmission continued from patient to patient. The logarithmically expanding epidemic curve is characteristic of patient-to-patient transmission, although this pattern may have been exaggerated by detection and recall biases. There were several potential vehicles for patient-to-patient transmission. A high proportion of HBV-infected patients were temporally linked to the practice and to other infected patients, and all of the specimens tested for antigenic subtype were identical. The *adw2* HBV subtype accounts for approximately 88% of the HBV infections in the southeastern United States, making the probability of finding *adw2* by chance alone in all 30 specimens from this outbreak equal to 1 in 50 ($P = .02$).[20]

In summary, we found more than 12 times the expected rate of patients reported with acute hepatitis B in a dermatology practice; most cases had had surgery in the practice during their incubation periods. Transmission from patient to patient appeared to result from failure to observe either universal precautions or sterile surgical technique. Finally, although HBV appears to have been freely transmitted, we found no evidence of transmission of HIV.

These findings strongly support efforts to increase awareness of blood-borne infections among physicians and to ensure that universal precautions are universally practiced. They also emphasize the importance of reporting blood-borne diseases to public health authorities, along with detailed exposure histories, and demonstrate once again that continuing review

of case reports by health departments is useful in identifying and controlling outbreaks. The outbreak described here was so insidious and of such long duration that it could easily have escaped detection if only the numbers of reported cases had been examined, without an epidemiologic review of potential sources of infection. Finally, consideration should be given to establishing standards of care for office-based procedures that would prevent the spread of blood-borne disease in much the same way that standards for food handling are used to prevent the spread of enteric disease. □

Salmonella Enteritidis Infections in France and the United States: Characterization by a Deterministic Model

Laurence Watier, PhD, Sylvia Richardson, PhD, and Bruno Hubert, MD

ABSTRACT

Objectives. Epidemiological surveillance can be used to identify problems, suggest hypotheses, and assess the effectiveness of preventive actions. These objectives are pursued in the analysis of the dynamic evolution of *Salmonella enteritidis* infections. In this analysis, development of the epidemic in France and the United States is compared.

Methods. This analysis is based on the formulation of a simple deterministic compartmental model, in which human contact with contaminated food is expressed in terms of a baseline transmission rate.

Results. In France, the baseline transmission rate, stable up until 1986, is multiplied by 2.3 in 1987 and by 4.1 in 1988. There is no evidence of a slowdown of the linear rate of increase. In the Middle Atlantic region of the United States, the linear increase of the epidemic is similar to that observed in France. From 1990 a potential effect of the preventive measures is observed.

Conclusions. The pattern of increase of the baseline transmission rate is similar in France and in the Middle Atlantic region of the United States. However, preventive measures, used in both areas, appeared more effective in the United States. (*Am J Public Health.* 1993;83:1694–1700)

Introduction

Salmonella enteritidis infections are a new and increasing public health problem in most European countries and in North America.[1] Consumption of raw or inadequately cooked eggs has been found to be the major source of infection.[2] Some countries, such as the United States, the United Kingdom, and France, have recently implemented control measures to identify and slaughter flocks of infected laying birds. To evaluate the efficacy of these measures, two sources of information are available: notification of outbreaks and identification of *Salmonella* isolates by a national reference center.

We propose a simple deterministic compartmental model to analyze the dynamic evolution of the total number of *S. enteritidis* isolates in a population, and we estimate this model on data from reference centers in France and the United States. In this model, we distinguish only two groups of individuals, susceptible and infected, since *S. enteritidis* is not known to confer any immunity.[3] A time-dependent transition rate from susceptible to infected is modeled at first in terms of both a baseline transmission rate (β_0) from the animal reservoir to humans and a seasonal multiplicative factor.

Such a model can help to achieve several public health objectives. Firstly, the estimation of β_0 for different time periods enables us to quantify the increase in cases of *S. enteritidis* observed in recent years and to compare the epidemic's development between countries. We show comparative results between France and the Middle Atlantic region of the United States.

Secondly, time components in the modeling of the transition rate from susceptible to infected can also be included to test if the time structure of potential environmental sources of contamination is reflected in the evolution of the indicator. Investigations in France from 1989 to 1990 showed that 52% of *S. enteritidis* outbreaks associated with eggs were due to free-range eggs from small holdings that were noncommercially distributed.[4] Thus, we included in the transition rate an indicator of the seasonal time pattern of egg laying of free-range hens.

Finally, model predictions were calculated to measure the impact of preventive measures taken in France since May 1989 and in the United States since February 1990.[5]

Material and Methods

Data

France. The data used in this study come from the National *Salmonella* Reference Center at the Pasteur Institute. This center receives *Salmonella* isolates from private or public laboratories for serotyping. Monthly notifications of identified *S. enteritidis* isolates are available dating from January 1978. The period analyzed includes 156 months of observations from January 1978 to December 1990. In addition, quarterly data on the number of isolates identified in laboratories other than the National Reference Center are also available and are used to check the stability of the distribution of isolates between the center and other laboratories.

Laurence Watier and Sylvia Richardson are with the Institut National de la Santé et de la Recherche Médicale, Villejuif, France. Bruno Hubert is with the Réseau National de Santé Publique, Saint Maurice, France.

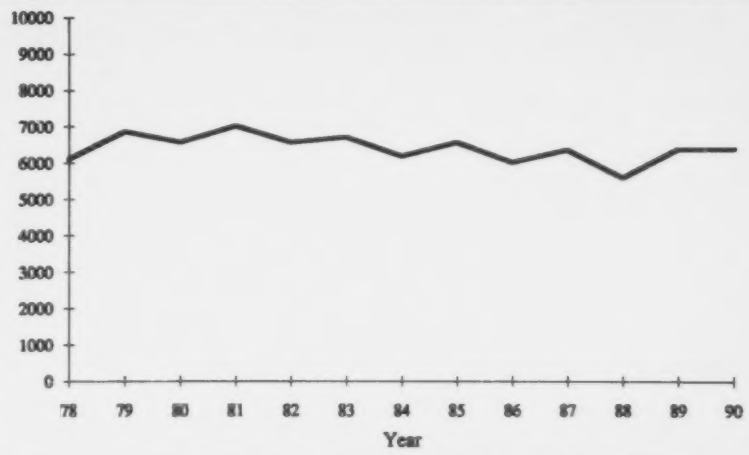
This paper was accepted June 29, 1993.

Editor's Note. See related annotation by Halloran (p 1667) in this issue.

Up until the end of 1988, the number of *Salmonella* isolates other than *S. enteritidis* and *S. typhimurium* was fairly constant (Figure 1); consequently, the observed increase in the number of *S. enteritidis* isolates in 1987 and 1988 (Figure 2) probably corresponds to a real increase in the incidence rather than to improved reporting. The mean-range plot confirms that the years 1987 and 1988 stand out (Figure 3). However, because of media coverage and some reorganization of laboratory analysis practices, two sources of bias were introduced. First, higher awareness of the dangers of *Salmonella* infections is reflected in a 16% increase in the yearly total of *Salmonella* isolates of all serotypes other than *S. enteritidis* and *S. typhimurium*. Second, it is known that in 1989, laboratories outside the National Reference Center started to equip themselves with antisera to be able to identify *S. enteritidis*. Indeed, for each year from 1978 to 1988, the center identified approximately 78% of all reported *S. enteritidis* isolates. The situation changed in 1989, however, and this proportion decreased to 74% and 47% for 1989 and 1990, respectively. Hence, model estimation is based on reference center data only up until the end of 1988. Yearly predictions for 1989 and 1990 are compared with observed yearly numbers after allowing for some bias corrections.

United States. The data analyzed come from the Centers for Disease Control and Prevention in Atlanta and are available for the period 1968 to 1990. The data are based on a passive laboratory-based *Salmonella* surveillance activity. The number of cases reported was found to represent from 1% to 5% of the real incidence of this infection.[6] The Middle Atlantic region of the United States was selected for analysis to maximize comparability with France data, given that similar climatic conditions prevail in both regions. The increase of reported cases started in 1984, providing a long stable period (Figures 3 and 4).

As in France, the system has inherent biases. However, Hargrett-Bean et al.[7] judged the data to be of sufficiently high quality to allow some insight as to the effectiveness of public health intervention.



[a]The values for 1989 and 1990 are obtained after allowing for a 16% mediatic increase.

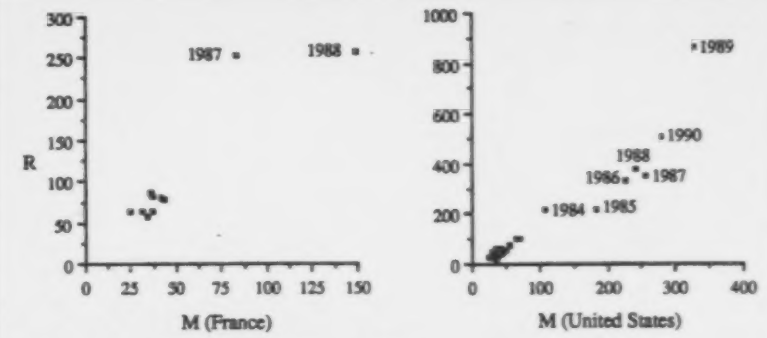
The Compartmental Susceptible-Infected Model

Person-to-person contact is considered of little importance in *Salmonella* transmission in contrast to classical infectious disease models.[8] Most new cases are related to the animal reservoir through foodstuff contamination. The dynamic evolution of *Salmonella* infections is analyzed using a simple deterministic compartmental model. The population is divided into subgroups, the susceptibles and the infecteds, and the flows between these two subgroups per unit of time are expressed. The model can be represented schematically as follows:

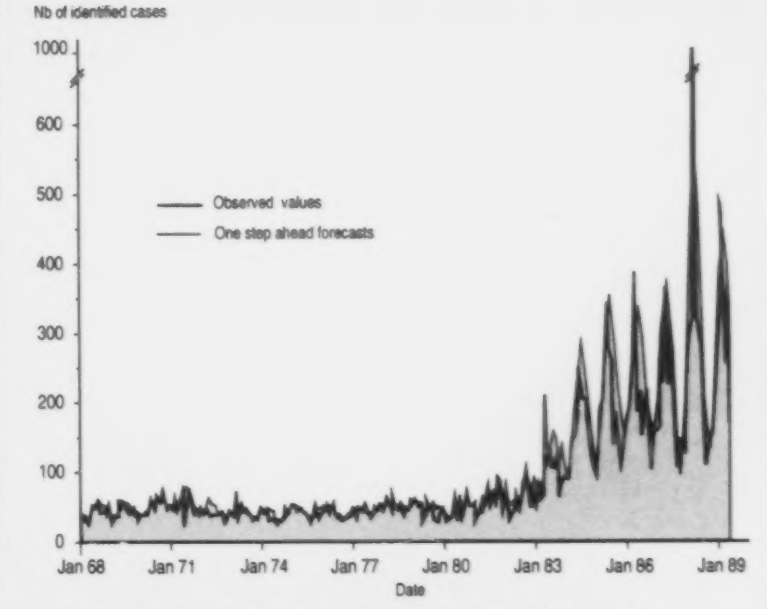
$$\boxed{NS(t)} \xrightarrow{f(t)} \boxed{NI(t)}, \qquad \boxed{NI(t)} \xrightarrow{\gamma} \boxed{NS(t)}$$

where $S(t)$ denotes the proportion of individuals not infected but susceptible to contract *S. enteritidis* infection at time t;



[a]The plot of the range against the mean for each seasonal period.

FIGURE 3—Mean-range plot[a]: mean and range for yearly *S. enteritidis* in France from 1978 to 1988 and in the Middle Atlantic region of the United States from 1968 to 1990.



[a]Model includes a baseline transmission rate (β_0) and a seasonal factor (β_1).

FIGURE 4—Comparison of the observed values and the one-step-ahead forecasts from the fitting of model 1[a] for *S. enteritidis* in the Middle Atlantic region of the United States from 1968 to 1990.

$I(t)$ denotes the proportion of individuals infected with *S. enteritidis* at time t;
N is the total population size, assumed to be constant; and
$f(t)$ and γ are the flows per unit of time between the two subgroups.

Note that $NI(t)$ represents the number of cases of the disease at time t.

The following hypotheses are made throughout:

1. Susceptible individuals become infected per unit of time at a rate $f(t)$, which represents a contact between individuals and contaminated foods; and
2. Infected individuals recover and become susceptible at a constant rate γ, with $1/\gamma$ representing the mean infection time.

Assuming a constant population size, these hypotheses lead to linear differential equations for $S(t)$ or $I(t)$, which can be easily solved (see Appendix).

Two models are proposed for the transmission rate $f(t)$. *Salmonella* multiplication is facilitated by a temperature of 20°C or higher, which explains the increased incidence of infection during summer months. Thus,

$$f(t) = \beta_0\left(1 + \beta_1 \sin\frac{2\pi t}{12}\right) \quad \text{(Model 1)},$$

where β_0 is a baseline transmission rate from the animal reservoir to humans and β_1 is a multiplicative seasonal effect of period 12 (Figure 5).

Investigations in France have tended to incriminate noncommercially distributed free-range eggs from small holdings, even though this category of eggs accounts for only 20% of French production.[4] Climatic conditions between November and April lead to an interruption of laying in nonindustrial free-range hens. This suggests a second model, including a further time component in the transmission rate $f(t)$:

$$f(t) = \beta_0\left(1 + \beta_1 \sin\frac{2\pi t}{12}\right) + \beta_2 g(t) \quad \text{(Model 2)},$$

where $g(t)$ is a periodic indicator function of the laying period and is equal to 1 between April and October, inclusively. The parameter β_2 is referred to as a seasonal laying effect (Figure 6).

Estimation

To be able to estimate $N\beta_0$, β_1, and, in some cases, $N\beta_2$ for fitting model 1 or 2 to the observed values of the number of new isolates $O(t)$ over a period $[t_0, t_1]$, it is necessary to suppose that $N\beta_0$, β_1, and $N\beta_2$ are constant over $[t_0, t_1]$. Clearly this is a reasonable assumption in a stable situation. In a situation in which an epidemic is developing, the time intervals chosen will be relatively short (say a year) so that this assumption holds approximately.

In the fitting of model 1, two coefficients—$N\beta_0$ and NC_1—are estimated with $C_1 = \beta_0\beta_1$ (see Appendix). To take into account possible time autocorrelation of the regression residuals, the coefficients $N\beta_0$ and NC_1 are estimated using a regression model with autocorrelated errors (procedure Autoreg of SAS/ETS[9]) and the value of $\hat{\beta}_1$ is deduced. To obtain the variance of $\hat{\beta}_1$, which is a multiple of $\hat{C}_1/\hat{\beta}_0$, the delta method is used. The fitting of model 2 proceeds along similar lines.

Prediction

In France, the stationary structure of *S. enteritidis* infections, which prevails until 1987, gives way to substantial increases in the following years (Figure 2). The US situation is similar, but the increase starts in 1984 (Figure 4). Under these conditions, forecasting is possible only if one is prepared to model the increase; with our approach, this entails predicting values of $N\beta_0$, β_1, and $N\beta_2$ by prolonging their observed trend.

Predictions are used as benchmarks to assess the impact of preventive measures. The observed values for the years after the start of the preventive measures are compared with the forecasts.

Results

Quantification of the Increase in the Baseline Transmission Rate in France

To confirm that the structure of the data was indeed perturbated in 1987, forecasts for that year were obtained, based on the previous observations. From March 1987 onward, the observed number of isolates lies well above the one-sided 95% upper confidence interval of the forecasts built from the 1978 to 1986 period, indicating that a nonstationary pattern of increase started in March 1987. Model 1 was thus estimated separately for the stable period of 1978 to 1986 and then year by year to characterize the increase.

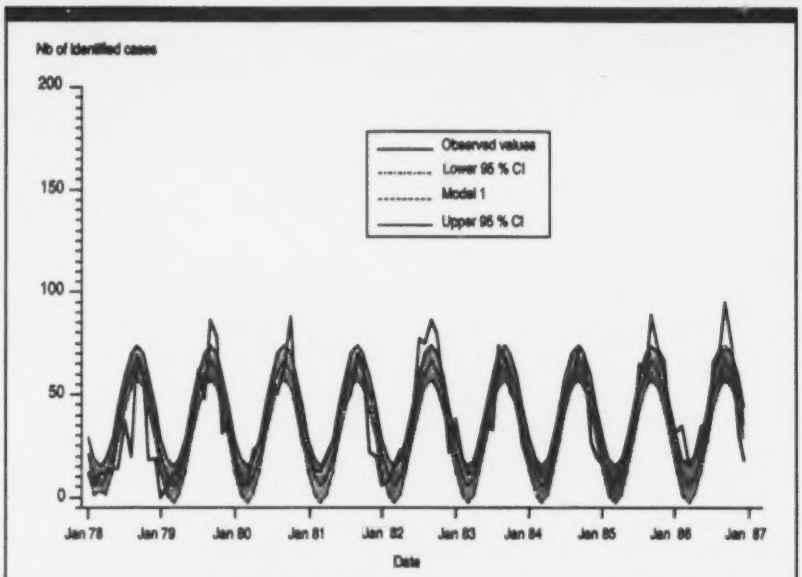
For the stable period, it was necessary to introduce autoregressive parameters at lags 1, 3, 8, 12, and 24. The autocorrelations at lags 1 and 3 reflect an expected short-term correlation, while those at lags 8, 12, and 24 are related to residual seasonality not accounted for by the deterministic part of the model.

All model parameters are clearly significant (Table 1). The seasonal multiplicative effect is fairly constant. On the other hand, there is a substantial increase of the baseline parameter β_0, which is first multiplied by 2.3 in 1987 and then by 4.1 in 1988. The sinusoidal shape of $Nf(t)$ in model 1 is illustrated in Figure 5 for the stable period, with parameters chosen in accordance with Table 1.

Quantification of the Increase in the Baseline Transmission Rate in the US Middle Atlantic Region

The same compartmental model was estimated separately for the stable period 1968 to 1983 and then year by year. For the stable period, the residuals were modeled with significant autoregressive parameters at lags 1, 3, and 11.

The parameter $N\beta_0$ is clearly significant over the eight periods (Table 2). The increase of β_0 seems to have diminished in 1990. For the stable period, the seasonality is less marked than it was for the French data, but the seasonal parameter β_1 is nonetheless significant. From 1984 onward, the seasonal effect is strengthened.



*$N\beta_0$ and β_1 have been replaced by their estimated values (36.1 and −0.8, respectively).

Note. Parameter estimates are indicated by a "^" with standard errors in brackets.
[a]Model includes a baseline transmission rate (β_0), a seasonal factor (β_1), and a seasonal laying effect (β_2).
[b]R_0 corresponds to the ratio of $N\hat{\beta}_0$ estimated in 1987 or in 1988 to its value for the stable period.
[c]R_2 corresponds to the ratio of $N\hat{\beta}_2$ estimated in 1987 or in 1988 to its value for the stable period.
*$P < .05$, **$P < .01$, ***$P < .001$, †$P = .057$, NS: $P \geq .1$, where P is the level of significance of the parameters.

It is noteworthy that the ratios R_0, which characterize the pattern of increase of β_0, are very similar between French and US data for the first 2 years of the epidemic. However, seasonal patterns are somewhat different between the two regions, with France exhibiting a more stable seasonal pattern.

Linking the Time Pattern of S. enteritidis *Infection to That of a Seasonal Laying Effect of Free-Range Hens*

In France, the involvement of flocks from small holdings in the epidemic can be tested by using model 2. This model was estimated on the stable period (with autoregressive parameters for the residuals at lags 1, 3, 8, 12, and 24) and then separately in 1987 and 1988. All parameters are clearly significant except for $N\beta_2$, which is nonsignificant in 1987 and only marginally significant in 1988 (Table 3). The seasonal multiplicative effect appears reasonably constant.

Comparison of Tables 1 and 3 shows that there is a fairly linear increase of the baseline parameter β_0 for the years 1987 and 1988 at a similar rate for both compartmental models. As expected, the addition of a parameter in model 2 resulted in a smaller value for the baseline rate $N\beta_0$. For the stable period, model 2 gives a significant improvement over model 1 ($\chi_1^2 = 4.04$, $P = .04$), and the seasonal laying effect parameter $N\beta_2$ is significant. In 1987, $N\beta_2$ is not significant, and the standard error of β_1 is increased. As seen in Figure 2, the increase in 1987 is extremely brutal, and neither model 1 nor 2 fits well. On the other hand, $N\beta_2$ is again significant in 1988. Overall, model 2 gives a reasonable fit.

To better visualize the two components of model 2—the sinusoidal part corresponding to model 1 and that relating to the seasonal laying effect ($g[t]$ in the appendix)—these components, as well as their sum for the stable period, are represented separately in Figure 6, with parameters chosen in accordance with Table 3.

Model 2 gave a poorer fit than model 1 for the stable period with the US data; consequently, the seasonal laying hypothesis does not seem appropriate for the United States.

Impact of Preventive Measures

France. Since May 1989, eggs from flocks found to be infected have been diverted to pasteurization plants or the flock has been destroyed. In 1989, for example, eggs were diverted to pasteurization plants for six flocks while three flocks were destroyed. To try to combat the emergence of *S. enteritidis* and reduce the number of infected birds, a working party composed of health officials and egg producers was set up. Specific recommendations concerning hygiene and poultry health checks were made during 1990. A convention was signed between the French state and the egg producers, whereby the state will compensate the producers for the eradiction of infected flocks and will reimburse costs for bacteriological analyses made in this context.

We have based our evaluation of preventive measures solely on the yearly totals for 1989 and 1990 since they can be globally corrected for bias.

Yearly forecasts of infected cases (as well as their standard errors) were computed with model 2 with parameter values replaced by their respective predictions. The parameter predictions were calculated under the assumption that the linear increase of the baseline rate observed for 1987 and 1988 was continuing. Precisely, predictions for parameters $N\beta_0$, NC_1, and $N\beta_2$ in 1989 and 1990 were obtained using equations corresponding to weighted regression of the estimated values of those parameters for three time periods: the stable period, 1987, and 1988. As expected, the parameter $\hat{\beta}_1$ was stable for both years, and the standard errors of $N\hat{\beta}_0$ and $N\hat{\beta}_2$ increased between 1989 and 1990.

The observed and bias-corrected numbers of isolates in the National Reference Center for 1989 and 1990 are given in Table 4. The bias-corrected figures were obtained after first allowing for a 16% increase in the total number of isolates observed (National Reference Center and laboratories) and then taking 78% of these isolates (see "Material and Methods" above).

In 1989, the bias-corrected number of isolates was higher than the predicted level, assuming a linear increase, and was close to the latter's upper 95% confidence interval. This seems to indicate that *S. enteritidis* contamination was accelerating. However, this acceleration did not appear to continue in 1990, as the predicted total was nearly identical to the bias-corrected value for that year. This points to a limited impact of preventive measures, but there is no evidence that the linear rate of increase was diminishing.

United States. In the United States, a voluntary state quality assurance program for *S. enteritidis* in flocks was implemented in February 1990.[5] Forecasts of $N\beta_0$ were calculated for the year 1990 under the assumption of a linear increase in the baseline parameter (Table 5). In 1990 the estimated value of $N\beta_0$ is below the lower 95% confidence interval for the predicted $N\beta_0$, and there is little overlap between their respective 95% confidence intervals. This indicates a potential effect of the preventive measures.

TABLE 4—Yearly Number of Isolates in the National *Salmonella* Reference Center (Observed and Predicted) for *S. enteritidis* in France for 1989 and 1990

Year	Observed (No Bias Correction)	Observed (Bias Correction)[a]	Predicted[b] (95% CI)
1989	3357	3068	2436 (2076, 2796)
1990	2133	3075	3103 (2378, 3828)

[a]After first allowing for a 16% increase in the total number of isolates observed (National Reference Center and laboratories) and then taking 78% of these isolates.
[b]Predicted by continuing the linear increase observed in 1987 and 1988.

TABLE 5—Comparison of Estimated and Predicted Baseline Parameter (β_0) for *S. enteritidis* in the Middle Atlantic Region of the United States for 1990

Year	Estimated (95% CI)	Predicted[a] (95% CI)
1990	128.1 (233.7, 328.3)	415.3 (384.3, 446.3)

[a]Predicted by continuing the linear increase observed between 1984 and 1989.

Discussion

The value of the model used here, which relies on strongly simplifying hypotheses, is that it summarizes the observed phenomenon with some easily interpretable parameters. A time periodical function similar to ours has been used in a measles transmission study.[10] By attempting to represent the underlying phenomenon, deterministic models lead to predictions that are based on explicit hypotheses. An alternative way to make predictions would be to use time series modeling, as was done for *Salmonella bovismorbificans*.[11] However, this purely statistical approach was found to perform less satisfactorily, and it permits neither time effects such as seasonal laying to be tested nor comparison with other data sources to be made.

Since the French data were reported through a system of passive surveillance, they represent only a fraction of all *Salmonella* infections. This surveillance system is understandably sensitive to any change in reporting practices. To assess the effects of variations in reporting, we examined trends in the proportion of isolates sent to the National Reference Center. Hence, even though we could not estimate a model on monthly data for the years 1989 and 1990, we were able to correct yearly totals for bias and compare the forecasted values to the observed ones (corrected for bias) to determine the impact of the preventive measures. Clearly, if monthly data for 1989 and 1990 could have been used, we could have characterized the effect of preventive measures by directly studying their influence on the values of $N\beta_0$ and $N\beta_2$, as was done with the US data. In the United States, such a blurring due to increased reporting is not thought to have occurred because the increase was limited to particular serotypes.[7] The observed stabilization of β_0 in 1990 for the US data could thus be attributed to the preventive measures.

Our results support the hypothesis that the observed increase of *S. enteritidis* started in 1987 in France, even though this phenomenon was present as early as 1984 in other European countries (England, Spain) and in the United States. For comparison between the Middle Atlantic region and France, only the simple seasonal model was used because there are fewer small-holding flocks in the Middle Atlantic region. The striking similarity of the rate of increase of β_0 between France and the US Middle Atlantic region suggests that common processes, probably connected with egg production in both countries, were involved in the *S. enteritidis* epidemic.

In France, the potential part played by free-range hen production from small holdings is shown by comparing the simple seasonal model and the model including the time pattern of seasonal laying. Note that the same time pattern is not observed in commercially distributed free-range eggs, which accounted for only 2.7% of the total 1990 production, since these flocks' rearing conditions ensure an uninterrupted laying throughout the year similar to industrial laying. The *S. enteritidis* increase could be due to the importation of infected birds, which are mainly introduced into nonindustrial flocks. From 1987, diversification of strains of hens corresponding to an increase in imports from other European countries was observed. Nevertheless, it is important to point out that, in common with any seasonal effect, this seasonal laying effect could be interpreted as a summer amplitude correction independent of a direct link with hen laying. It would thus be interesting to see whether this particular time pattern is also present in the structure of indicators of *S. enteritidis* infections in other countries where, as in France, free-range hens in small holdings contribute to some extent to the egg production. □

APPENDIX—The Compartmental Susceptible-Infected Model

$$\boxed{NS(t)} \xrightarrow{f(t)} \boxed{NI(t)}, \qquad \boxed{NI(t)} \xrightarrow{\gamma} \boxed{NS(t)}$$

where $S(t)$ denotes the proportion of individuals not infected but susceptible to contract *S. enteritidis* infection at time t;
$I(t)$ denotes the proportion of individuals infected with *S. enteritidis* at time t;
N is the total population size, assumed to be constant, and $f(t)$ and γ are defined as in the text.

Note that $NI(t)$ represents the number of cases of the disease at time t. This diagram leads to differential equation systems:

(1) $\frac{d}{dt}(NI(t)) = f(t)\,NS(t) - \gamma NI(t)$,

(2) $\frac{d}{dt}(NS(t)) = -\frac{d}{dt}(NI(t))$ (because the total population is assumed to be constant).

Under the hypothesis that the susceptible population is much larger than the infected one, we can suppose that $NS(t) \approx N$, and then $Nf(t)$ in (1) corresponds to the appearance of new cases at time t. In other words, $Nf(t)$ models the time evolution of the incidence of the disease. The system leads (after division of (1) by N) to the differential equation

$$\frac{d}{dt}I(t) + \frac{I}{\gamma(t)} = f(t),$$ which can be integrated to

$$I(t) = e^{-\gamma t}\int_0^t e^{\gamma s} f(s)\,ds + I(0)\,e^{-\gamma t}.$$

If we work with prevalence data, we use the solution $NI(t)$ to model the data. In our case, we dispose of the number of new isolates $O(t)$ at time t. So we directly fit $Nf(t)$ to our data.

Model 1: $f(t) = \beta_0\left(1 + \beta_1 \sin\frac{2\pi t}{12}\right)$, and we fit:

$$O(t) = N\beta_0 + NC_1 \sin\frac{2\pi t}{12} + u_1(t),$$

where $C_1 = \beta_0\beta_1$ and $u_1(t)$ represents an autocorrelated error term with zero mean.

Model 2: $f(t) = \beta_0\left(1 + \beta_1 \sin\frac{2\pi t}{12}\right) + \beta_2\, g(t)$,

with $g(t) = \begin{cases} 1 & \text{between } a + 12i \text{ and } b + 12i \text{ inclusive, } i \geq 0 \\ 0 & \text{otherwise,} \end{cases}$

and we fit:

$$O(t) = N\beta_0 + NC_1 \sin\frac{2\pi t}{12} + N\beta_2\, g(t) + u_2(t),$$

where $C_1 = \beta_0\beta_1$ and $u_2(t)$ represents an autocorrelated error term with zero mean.

Note that the estimated parameters are $N\beta_0$ and $N\beta_2$. Because we made the hypothesis of a constant population N, we can interpret the evolution of the baseline transmission rate β_0 and of the seasonal laying effect β_2.

The Health Effects of Swimming at Sydney Beaches

ABSTRACT

Objectives. The purpose of the study was to determine the health risks of swimming at ocean beaches in Sydney, Australia.

Methods. From people attending 12 Sydney beaches in the period from December 5, 1989 to February 26, 1990, we recruited a cohort of 8413 adults who agreed to participate in this study. Of these, 4424 were excluded either because they had been swimming in the previous 5 days or because they reported a current illness. Of the remainder, 2839 successfully completed a follow-up telephone interview conducted within 10 days after recruitment. We recorded reported respiratory, gastrointestinal, eye, and ear symptoms and fever that occurred within the 10 days between initial interview on the beach and the follow-up interview.

Results. A total of 683 participants (24.0%) reported experiencing symptoms in the 10 days following initial interview. Of these, 435 (63.7%) reported respiratory symptoms. Swimmers were almost twice as likely as nonswimmers to report symptoms. There was a linear relationship between water pollution and all reported symptoms with the exception of gastrointestinal complaints.

Conclusions. Swimmers at Sydney ocean beaches are more likely to report respiratory, ear, and eye symptoms than beachgoers who do not swim. The incidence of these symptoms increases slightly with increasing levels of pollution. (*Am J Public Health.* 1993;83:1701–1706)

Introduction

The disposal of human sewage through ocean outfalls adjacent to recreational bathing areas and, before that, into Sydney Harbour has been a contentious issue since the early years of the colony in New South Wales.[1] Apart from the aesthetic objections, there is a long-standing concern that bathing in polluted waters poses a risk to the health of the estimated 3 million people who use these beaches annually.[2]

Seventy percent of Sydney's sewage is discharged through three ocean outfalls at North Head, Bondi, and Malabar. Each outfall releases primary treated sewage into coastal waters, 150 to 650 ML per day in dry weather and 700 to 2400 ML per day in wet weather.[3] The sewage system is designed to overflow into the storm-water system at times of high rainfall to cope with this large increase in volume in wet weather. Fecal contamination of swimming beaches can occur when the sewage plume from these outfalls, under the influence of winds or currents, moves onto the beach and via discharge from storm-water drains, many of which discharge directly onto beaches.

Studies at ocean and freshwater sites in the United States,[4–6] Canada,[7,8] Egypt,[9] and Israel[10] have shown a variable relationship between gastrointestinal, respiratory, ear, and skin symptoms and indices of sewage pollution of bathing water. The results of these studies are not necessarily applicable to Sydney's beaches because of differences in dilutive factors, water temperature, ocean currents, and method of sewage treatment and their potential effects on the survival of pathogenic organisms[11] in bathing waters.

In the summer of 1989, the New South Wales Health Department released the results of a survey of bathing water quality that showed that one third of all samples tested at many popular Sydney beaches failed to meet existing water quality criteria.[12] A wave of media and community protest followed. Bodies such as the Australian Surf Lifesaving Association, whose members are the very icons of Australian beach culture, added their voices to the call for an urgent review of bathing water quality in Sydney. Physicians practicing in beachside suburbs reported an increase in the incidence of ear infections, gastroenteritis, and other viral illnesses that could be attributed to ocean bathing.[13] The desertion of beaches that followed these reports had major economic implications for local businesses and for Sydney's reputation as an international tourist destination. Against this background the Sydney Beach Users Study was commissioned, with a brief to investigate the relationship between ocean swimming at Sydney's beaches and illness. An advisory committee comprising representatives from the state government and consumer groups was formed to oversee the planning and execution of the

TABLE 1—Geometric Mean Bacterial Counts of Beach Water Samples, by Organism and Time of Collection, Sydney Beach Users Study, 1989/90

	Colony-Forming Units per 100 mL			No. Samples Passed[a]	No. Samples Failed[a]	Total No. Samples[b]
	Median	Maximum	Mean			
Fecal coliforms						
Morning	26.2	20000.0	591.4	191	42	233
Afternoon	15.9	25570.9	389.1	203	25	228
Fecal streptococci						
Morning	16.4	1356.5	65.9	...[a]	...[a]	229
Afternoon	11.5	1263.3	42.7	...[a]	...[a]	223

[a]For coliforms, a sample failed if the geometric mean count exceeded 300 colony-forming units per 100 mL or if any one reading was greater than 2000 colony-forming units per 100 mL. There is currently no recreational-water quality standard for fecal streptococci in New South Wales.
[b]A total of 482 samples were tested; 21 tests for fecal coliforms and 30 tests for fecal streptococci did not yield usable results.

study. This paper reports the results of this epidemiological study.

Methods

Subjects

Subjects for this cohort study were selected from persons attending 12 designated Sydney beaches on a total of 41 sampling days including weekends, public holidays, and one randomly selected weekday between December 5, 1989, and February 26, 1990. We selected the 12 most popular beaches in the metropolitan area, as assessed by the Surf Lifesaving Association, to recruit subjects.

On each of the study days, beachgoers at 6 of the 12 beaches were approached to obtain consent to participate in the study. The 6 beaches selected on any day included 2 each from the northern, eastern, and southern areas. We used a quota sampling technique for selection of subjects at individual beaches, setting equal quotas for each beach on each sampling day. Each beach was divided into three sectors, defined by the position of the swimming area flags erected by the lifesavers (lifeguards). The allotted quota for the beach was divided equally among the three sectors. Trained interviewers recruited subjects, starting at the center of each sector and moving in a clockwise fashion until the quota for that sector had been reached. To minimize the inclusion in the study of family or social groups, we specified that potential subjects be at least 3 m apart.

To quality for inclusion, a respondent had to be 15 years old or older and had to agree to both an initial beach interview and a follow-up telephone interview. We excluded children younger than 15 years of age because of the problems involved in obtaining consent from minors for biomedical research. At the beach interview the interviewer introduced the respondent to the survey, collected basic demographic data, and asked whether the respondent had swum anywhere in the previous 5 days or had any condition that precluded swimming on the day of the interview.

Subjects were excluded from the study if they reported having been swimming in the 5 days prior to the beach interview or having an illness that prevented them from swimming on the interview day.

Interviewers telephoned study participants 7 to 10 days after the initial interview to elicit details of symptoms of illness in the previous week, attendance at a doctor's office, absence from work, and whether the subject had been swimming at any time between the initial and follow-up interviews. Respondents were asked whether they had experienced vomiting; diarrhea; cough, cold, fever, or symptoms suggestive of flu; or ear or eye infections since the day of the beach interview.

Field interviewing, clerical checking, data entry, and initial computer editing were performed by AGB McNair, a division of AGB Research Australia Pty Ltd under contract to the New South Wales Health Department.

Exposure Assessment

We defined swimming as immersion of the face and head in water. At follow-up the interviewer asked whether the subject had swum on the day of the beach interview and asked the subject to estimate the amount of time spent in the water.

Water samples were taken on the same days and at the same beaches on which interviews were conducted. Health department surveyors collected morning and afternoon samples on each day from sites approximately at the midpoint of each sector of the beach. As nearly as could practicably be achieved, interviewing of respondents at selected beaches was done in the period in which water samples were taken. A standard protocol for the collection of 250 mL of water at a depth of 30 to 45 cm was used. Samples were refrigerated at 4°C and transported for analysis at the Division of Analytical Laboratories of the New South Wales Health Department. Recommended standard methods were used to count fecal coliforms[14,15] and fecal streptococci.[16]

We defined fecal contamination of beachwater as low if there was compliance with the current New South Wales Department of Health standard—geometric mean coliform count not exceeding 300 colony-forming units per 100 mL and no single sample exceeding 2000 colony-forming units per 100 mL—and high if these levels were exceeded.

Statistical Methods

We used the Statistical Analysis System (SAS)[17] for tabulations and subsequent statistical modeling. Unconditional logistic regression, using both the CATMOD procedure in SAS (Version 6.03) and the MULTLR program, was used to model the main effects and covariates on the probability of reporting symptoms.[18] Point and interval estimates in the presence of interaction were performed according to the methods of Kleinbaum et al.[19]

We assessed the health effects of swimming in polluted water by fitting a series of logistic regression models to the data to adjust—for age, sex, and a history of subsequent swimming—estimates of odds of reporting specific symptoms in swimmers compared with nonswimmers. Two variables denoted exposure to polluted water in these models: swimming duration and a measure of bacterial count in the water. The bacterial count was derived from the geometric or arithmetic mean organism count or from the maximum organism count of all water samples collected on that beach on the day of the beach interview.

These logistic regression models were fitted separately for each outcome, that is, (1) any reported symptoms, (2) respiratory symptoms, (3) fever, (4) eye symptoms, (5) ear symptoms, and (6) gastrointestinal symptoms.

Results

Water Sampling

Of 482 individual water samples tested, 461 yielded usable results. Of these, 67 (14.5%) failed to meet the water quality criteria set by the New South Wales Department of Health. Summary results of water testing for both fecal contamination indices measured, coliforms and fecal streptococci, are presented in Table 1. There was a strong correlation between a "pass" on the morning test and a "pass" in the afternoon test. (A water sample was categorized as a "pass" if the geometric mean fecal coliform count was below 300 colony-forming units per 100 mL.) On days when the water failed the morning test, there was a 50% chance of its also failing the afternoon test.

Exposure and Reported Symptoms

Of the 9650 persons who were approached on the selected beaches, 8413 (87.2%) agreed to participate. Of these, we excluded 325 (3.9%) because they had illnesses that prevented them from swimming on that day and 4099 (48.7%) because they reported that they had been swimming in the previous 5 days. Of the remaining 3989 persons, we were able to contact 2968 (74.4%) by telephone for a follow-up interview. Young males were the most likely not to respond at the follow-up interview. The age and sex of those refusing to participate, those excluded because of prior swimming or illness, and those enrolled in the study were similar (Table 2).

We excluded 12 subjects from the analysis because of missing age and sex data and a further 117 subjects because of missing data on pollution levels on the day of beach interview. This left 2839 subjects available for analysis. Of this group, 915 (32.2%) reported that they had not swum on the day of the beach interview. Only 303 (10.7%) of the subjects swam on days on which high pollution levels were recorded.

A total of 683 subjects (24.0%) reported experiencing symptoms in the previous week; of these, 435 (63.7%) reported respiratory symptoms. The prevalence of reported fever and respiratory, eye, ear, and other symptoms increased with increasing bacterial counts measured on the day of initial interview. Gastrointestinal symptoms, which were reported by 4.1% of the subjects, did not increase with increasing counts of fecal bacteria (Table 3).

The prevalence of respiratory symptoms in young people aged 15 through 25 years was high, irrespective of swimming status or pollution level. Only in older people did the incidence of respiratory symptoms rise with increasing levels of pollution. The prevalence of other reported symptoms did not vary significantly across age groups (Table 4).

Swimmers were almost twice as likely as nonswimmers to report symptoms (odds ratio [OR] = 1.9; 95% confidence interval [CI] = 1.4, 2.4), after adjustments were made for age and sex. Symptoms were reported less frequently by people who swam between the original and follow-up interviews (Table 5). There was no evidence that swimmers were deterred from entering the water because it was or appeared to be contaminated.

We assessed the effect of increasing pollution levels by comparing the estimated odds ratios at different levels of pollution for swimmers vs nonswimmers. As the counts of fecal bacteria measured on the day of original interview rose, swimmers were more likely to report all symptoms except gastrointestinal symptoms

Fever	2.1	0.6, 7.0	4.7	1.0, 22.5	9.0	1.9, 43.5		...[b]
Any gastrointestinal symptom	4.6	1.9, 4.9	3.1	0.7, 13.0	3.4	0.7, 18.0		...[b]

Note. Results are for swimmers who swam only on the day of the original interview and who swam for longer than 30 minutes. CI = confidence interval; cfu = colony-forming units of fecal coliforms.
[a]Adjusted for age, sex, and swimming duration; the reference category is nonswimmers.
[b]Highest category > 1000 cfu/100 mL.

(Table 6). We plotted the estimated odds ratios of swimmers' reporting symptoms (within the group of swimmers only, using the lowest pollution level as the reference group) against pollution level (Figure 1). The linear relationship between pollution level and the odds of reporting symptoms can be expressed mathematically by the formula OR = 1 + 0.0000921 ln (Geometric Mean Coliform Count).

Substituting the arithmetic mean for the geometric mean coliform count in the logistic model slightly improved the fit of this model to the data ($\chi^2 = 2.18$, $P < .25$). Counts of fecal streptococci were worse predictors of the odds of reporting symptoms than were counts of fecal coliforms.

We assessed the effect of swimming duration on health by comparing information on those who swam for less than 30 minutes and those who swam for more than 30 minutes, but only in those subjects who did not swim between interviews. Those who swam for longer than 30 minutes were 4.6 times more likely to develop gastrointestinal symptoms than were nonswimmers or those who swam for less than 30 minutes (Table 7).

Discussion

The cohort design used in this study is an adaptation of that used in similar studies in other countries.[6–9] The design has the explicit aim of isolating exposure to a particular day so that the measurements of beach pollution on that day can

be used as a proxy measure of the dose of potentially pathogenic microorganisms. We attempted to improve on this design by increasing the frequency of pollution measurement on study days and by including data on swimming duration in the follow-up questionnaire. The exclusion of children, done primarily for ethical reasons, reduces reporter bias but limits the applicability of our results to people younger than 15 years.

There are at least two explanations for the lower prevalence of reported symptoms in those who swam between interviews. In some people, illness may have prevented swimming between the day of the original interview and the follow-up call. Conversely, those people who did swim subsequently may have included regular swimmers who have some immunity to pathogenic microorganisms in ocean water.

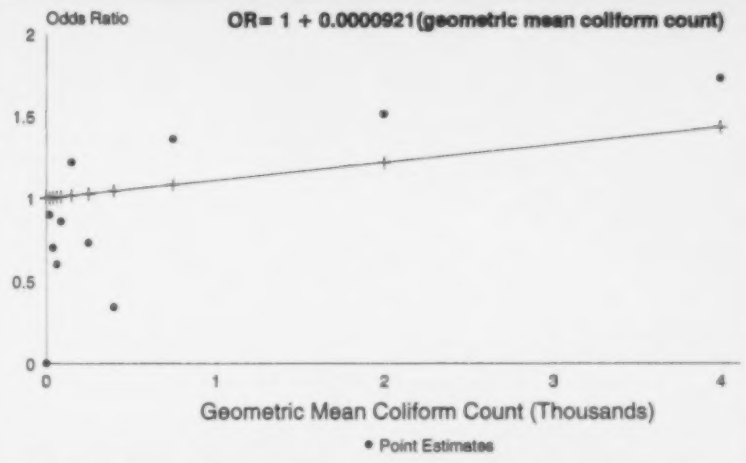
Our results provide evidence that the risk of swimming-related illness increases with increasing pollution levels. The estimates of the magnitude of the slope of the relationship between pollution levels and all symptoms are similar to those obtained elsewhere.[8] The assumption of a linear relationship between illness and pollution levels may have overestimated the risk of illness at lower pollution levels. If a minimum infective dose of microorganisms acquired while swimming is required to cause illness then we should see a threshold pollution level below which illness did not occur. Our data suggest that such a threshold may in fact be present (see Figure 1).

The increases in risk of respiratory, ear, and eye symptoms account wholly for the increases in illness observed. Enteroviruses, the commonest viruses present in sewage effluent, can cause respiratory symptoms.[20] They also persist in marine sediments and water for many months.[21] In a pilot study of viruses and pathogenic bacteria in waters at two Sydney beaches,[22] 2 of 10 samples taken from bathing areas contained enteroviruses; both vaccine-strain polioviruses. However, enteroviruses were isolated in 63% of samples collected from sewage effluent or the sewage plume. All counts of fecal indicator organisms in bathing areas in this study were below the current New South Wales standard, and it may therefore have underestimated the numbers of viruses present in polluted conditions.

Over the 41 days of data collection the beaches were cleaner than usual, thereby limiting the precision of our estimates of the odds of pollution-related symptoms at high levels of pollution. Of the water samples tested in our study, 14% exceeded the current New South Wales standard. Daily surveillance of ocean water quality at seven Sydney beaches between 1983 and 1987[3] showed that five of these beaches exceeded the current standard on more than 30% of occasions in dry weather. In wet weather, six beaches failed more than 50% of the tests.

Our data do not support the contention that minor barotrauma associated with surf swimming is the cause of an increase in reported respiratory symptoms in bathers. If this were true, we would expect an increase in reported respiratory symptoms with increasing swimming duration. We found no such increase.

Reported gastrointestinal symptoms showed no increase with increasing pollution levels. The prevalence of gastrointestinal symptoms (4.1%) was similar to that reported in other studies.[6-9] A dose–response relationship between indices of bacterial pollution and gastrointestinal symptoms has been an inconsistent finding and has been most clearly demonstrated in children, who were excluded from our study. Some of these studies did not fully adjust for confounders such as age and reporter and interviewer bias, and they may have overestimated the magnitude of the dose–response effect.[23] In the study design we used self-reporting of symptoms and exclusion of children to minimize reporter bias. We did not use



Note. ORs are adjusted for age, sex, and swimming duration; swimmers in water with 10 colony-forming units of fecal coliforms per 100 mL were the reference category.

[a]Adjusted for age and sex; the reference category is nonswimmers.

any clinical confirmation of reported symptoms. Measurement error of this kind would be nondifferential and would therefore bias our estimate toward not showing an effect. There was some evidence of an increase in risk of reporting gastrointestinal illness with increased swimming duration. Swimming duration may be a proxy measure of the volume of ingested seawater, which may directly cause symptoms.

The results of this study suggest that, at Sydney's beaches, fecal coliforms are marginally better predictors of reported symptoms than fecal streptococci. These results are at odds with other studies in which fecal coliforms have been poorer predictors of adverse health outcomes than either streptococci or staphylococci. This discrepancy may be explained by the different relative survival of these microorganisms in effluent that is not chlorinated and in oceans that are warmer than those around North America.

A technical issue prominent in the public debate on ocean water quality was the choice of an appropriate summary measure of water quality. Bacterial counts in water samples are inherently variable and concurrent samples from the same site can differ by orders of magnitude. The geometric mean of serial measurements is traditionally used as a summary index of pollution. Criticism of the use of a geometric mean of bacterial counts has focused on the apparent "leveling" of the data,[1] thereby understanding the true level of pollution. Furthermore, use of the geometric mean count rather than, say, the arithmetic mean or the daily maximum may introduce bias.[24]

To address these concerns we substituted the arithmetic mean and the daily maximum for the geometric mean coliform in the logistic models. There was a small improvement in the fit of the data when the arithmetic mean was used, and this summary measure is therefore preferable. It also has the advantage of being more easily comprehended by the public.

In conclusion, we found a consistent increase in reported illness with increasing pollution levels of all symptom categories except gastrointestinal symptoms. This dose–response relationship provides a quantitative basis for developing a health-based standard for ocean water quality on Sydney's beaches. □

Cat Scratch Disease in the United States: An Analysis of Three National Databases

Lisa A. Jackson, MD, Bradley A. Perkins, MD, and Jay D. Wenger, MD

ABSTRACT

Objectives. Current knowledge of the epidemiology of cat scratch disease is based primarily on information from case series. We used three national databases to obtain more representative data to determine the incidence and demographics of cat scratch disease.

Methods. Records coded with the diagnosis of cat scratch disease from two hospital discharge databases and an ambulatory care database were analyzed. Costs of diagnostic tests and hospitalization were obtained from a sample of providers and published data.

Results. The incidence of patients discharged from hospitals with a diagnosis of cat scratch disease was between 0.77 and 0.86 per 100 000 population per year. Fifty-five percent of the case patients were 18 years of age or younger. Males accounted for 60% of cases. Incidence varied by season; approximately 60% of case patients were discharged in the months September through January. The estimated incidence of disease in ambulatory patients was 9.3 per 100 000 population per year. On the basis of these rates, we estimated the annual health care cost of the disease to be more than $12 million.

Conclusions. The rates and seasonality of cat scratch disease found in this study were consistent with previous reports. Adults represented a higher percentage of the total than reported in previous case series, suggesting that the disease may affect more adults than previously recognized. (*Am J Public Health.* 1993;83: 1707–1711)

Introduction

Cat scratch disease is classically characterized by persistent regional lymphadenopathy in an area draining lymph from the site of a recent cat scratch. Recent evidence suggests that *Rochalimaea henselae,* a bacterium that has been isolated from patients with bacillary angiomatosis,[1] is associated with cat scratch disease.[2–4] Case series have been the primary source of information on the age distribution, seasonality, and clinical characteristics of cat scratch disease since it was first recognized in the United States in the 1940s.[5] Although these reports have contributed greatly to our understanding of the disease, they are subject to geographic and referral biases, and because they are not population-based, they cannot be used to determine rates of disease. Advances in identifying the etiology of the disease, with the associated implications for improvement in diagnostic capabilities and treatment, emphasize the need to determine the magnitude of the disease and the population primarily affected by it. We used information from two large hospital discharge databases and an ambulatory care database to describe the epidemiologic features and estimate the health care costs of cat scratch disease in the United States.

Methods

Abstracted hospital discharge records from the Commission on Professional and Hospital Activities (CPHA) and the National Hospital Discharge Survey (NHDS) were analyzed. Participation in CPHA is voluntary and the percentage of short-stay hospitals participating varies by state and year. The ratio of the number of discharges from CPHA hospitals in a state in a given year to the total number of hospital discharges for the state (as reported by the American Hospital Association) in that year was used to calculate a weight variable to allow extrapolation to national estimates. Records from 1983 through 1989 with cat scratch disease as any one of as many as 22 discharge diagnoses coded were analyzed.

NHDS is a continuous national survey of inpatient utilization of short-stay hospitals conducted by the National Center for Health Statistics (NCHS). Survey data are abstracted from a sample of medical records of patients discharged from nonfederal short-stay hospitals chosen systematically on the basis of hospital size. A weight variable is provided by NCHS to allow extrapolation to national or regional estimates. Records from 1978 through 1989 with cat scratch disease as any one of as many as seven discharge diagnoses coded were analyzed. The relative standard error for the number of records with a diagnosis of cat scratch disease was calculated using information provided by NCHS[6] and was used to determine the 95% confidence intervals (CIs) for the weighted estimates.

The National Ambulatory Medical Care Survey is conducted intermittently by NCHS and provides data from outpatient records selected from a national sample of office-based physicians. A weight variable is provided by NCHS to allow extrapolation to national or regional estimates. Surveys were conducted in 1980,

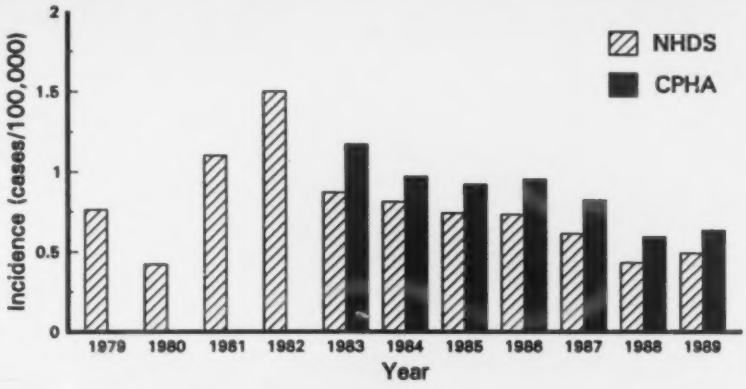
This paper was accepted April 9, 1993.



Note. CPHA records from 1983 through 1989 and NHDS records from 1979 through 1989 were analyzed.

FIGURE 1—Incidence of hospitalizations for cat scratch disease, estimated from National Hospital Discharge Survey (NHDS) and Commission on Professional and Hospital Activities (CPHA) data sets, by year.

1981, 1985, and 1989; records with cat scratch disease as any one of the three physician diagnoses coded from these surveys were analyzed. The relative standard error could be calculated from the information provided by NCHS records only for 1985; this figure was used to determine the 95% confidence interval of weighted estimates for that year.

All diagnoses and procedures were coded with *International Classification of Diseases, 9th Revision: Clinical Modification* (ICD-9-CM) codes.[7] Code 078.3 (cat-scratch disease) was used to extract records with the diagnosis of cat scratch disease, and codes 40.0 (incision of lymphatic structures), 40.1 (diagnostic procedures on lymphatic structures), 40.11 (biopsy of lymphatic structure), 40.19 (other diagnostic procedures on lymphatic structures), 40.2 (simple excision of lymphatic structure), 40.21 (excision of deep cervical lymph node), 40.23 (excision of axillary lymph node), 40.24 (excision of inguinal lymph node), 40.29 (simple excision of other lymphatic structure), and 40.3 (regional lymph node excision) were used to extract records with lymph node procedures (excluding excision of internal mammary lymph nodes and radical excision or dissection of any lymph node).

Population estimates were obtained from the US Bureau of the Census.[8] All rates are expressed as cases per 100 000 population per year. Regions listed correspond to those described by the Bureau of the Census. All calculations were performed after records were weighted as described above.

Cost estimates for diagnostic tests and invasive procedures were based on the average price quoted by a sample of providers in the Atlanta metropolitan area in 1992. The cost of an office visit,[9] inpatient day at a community hospital,[10] and hospital consultation[9] were obtained from published data and were adjusted to 1992 dollars at a rate of increase of 6% per year.[11]

Results

Hospitalized Patients

Cat scratch disease was listed as a diagnosis in 2828 records reported in CPHA from 1983 through 1989 and 95 records reported in NHDS from 1979 through 1989; these records represented, in each database, less than 0.01% of the total number of records. After weighting, we estimated averages of 2060 (CPHA) and 1787 (NHDS) (95% CI = 922, 2652) discharges per year of patients with a diagnosis of cat scratch disease. The estimates of the annual incidence of patients discharged with a diagnosis of cat scratch disease were 0.86 (CPHA) and 0.77 (NHDS) per 100 000 population. The incidence estimates varied from 0.59 per 100 000 population in 1988 to 1.2 per 100 000 population in 1983 for CPHA and from 0.42 per 100 000 population in 1980 to 1.5 per 100 000 population in 1982 from NHDS (Figure 1).

The age and sex distributions, regional rates, and seasonal patterns of cases derived from the CPHA and NHDS data sets were similar. Both sets showed a higher proportion of cases among children (persons 18 years of age and younger) than adults. Forty-five percent of CPHA and 50% of NHDS case patients were younger than 15 years, and 54% of CPHA and 57% of NHDS case patients were 18 years old or younger. The highest incidence in the CPHA data set, 2.0 per 100 000 population, was in the 5 through 14-year-old age group; in the NHDS data set the peak incidence, 2.1 per 100 000, was in children younger than 5 years (Figure 2). Males were disproportionately represented. There was a higher incidence in males than in females in both data sets—1.0 and 0.93 per 100 000 males vs 0.69 and 0.60 per 100 000 females for CPHA and NHDS, respectively. Fifty-eight percent of all case patients in the CPHA data set and 60% of all case patients in the NHDS data set were males. The incidence of cat scratch disease was higher among Whites than Blacks. In the CPHA data set, the average incidence was 0.87 per 100 000 for Whites and 0.53 per 100 000 for Blacks; in the NHDS data set the average incidence was 0.78 per 100 000 for Whites and 0.5 per 100 000 for Blacks. Incidence varied by geographic region; in both data sets, the average annual incidence was lower in the West and higher in the South than in the nation as a whole (Figure 3).

Seasonal variation was observed; 59% of CPHA and 61% of NHDS case patients were admitted in the 5 months from September through January (Figure 4). Seasonality was more pronounced for the Midwest region, in which 64% of CPHA and 76% of NHDS case patients were admitted during those 5 months.

Previously described manifestations of cat scratch disease, including encephalopathy, seizures, thrombocytopenia, erythema nodosum, neuritis (brachial, peripheral, or lumbosacral), hepatitis, and osteomyelitis, were reported in 4.9% of CPHA and 8.5% of NHDS records. No patient had a diagnosis of Parinaud's oculoglandular syndrome. No fatalities were reported in NHDS; one death was recorded in CPHA, for a case-fatality rate of 0.03%.

A lymph node procedure—incision, excision, or biopsy—was recorded for 56% of CPHA and 56% of NHDS cat scratch disease case patients. Patients with cat scratch disease accounted for 0.8% of all lymph node procedures recorded for all patients in the NHDS data set from 1979 through 1989. This percentage was higher for younger age groups; cat scratch disease patients accounted for 2.7% of all patients younger than 15 years with lymph node procedures and for 7.4% of all 5- through 14-

year-old patients with lymph node procedures. Cat scratch disease patients accounted for 1.3% of all lymph node procedures performed from September through January and for 15.6% of those performed during this period in the 5- through 14-year-old age group. Data on all patients with lymph node procedures in the CPHA data set were not available.

The average duration of hospitalization for case patients in each database was 4 days (ranges: 0–373 days [CPHA] and 0–16 days [NHDS]). Approximately half of the case patients in both sets stayed 2 days or less.

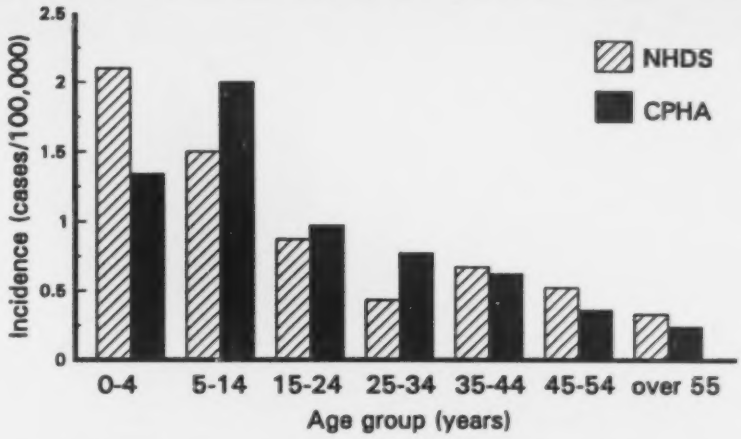
Ambulatory Patients

A total of 10 records with a diagnosis of cat scratch disease were recorded in the National Ambulatory Medical Care Surveys: 1 in 1980, 1 in 1981, 8 in 1985, and 0 in 1989. After weighting, the estimated total number of outpatient cases of cat scratch disease for those years was 87 484, for an average of 22 000 cases per year. Relative standard error could be calculated for 1985 records only; the 95% confidence interval for the estimate of 63 663 cases in 1985 was 0, 147 264. Annual incidence varied from 0 in 1989 to 26.9 per 100 000 population in 1985; the average annual incidence was 9.3 per 100 000 population. All case patients were White; 62% were male. The average age was 22 years (range: 5–33 years), and 54% were younger than 25 years. A fall/winter peak was not seen; only 33% of cases occurred between September and January.

Estimated Cost of Disease

A clinical diagnosis of cat scratch disease requires the fulfillment of three of four criteria: (1) history of cat contact, with the presence of a scratch or primary lesion; (2) positive cat-scratch skin test antigen response; (3) negative laboratory results for other causes of lymphadenopathy; and (4) characteristic pathologic findings of a lymph node.[12,13] The skin test antigen is not standardized, licensed, or widely available; thus, to fulfill the diagnostic criteria a lymph node biopsy and laboratory tests to exclude other causes are usually needed. Therefore, most patients with suspected cat scratch disease would be expected to have a complete blood count, rapid plasma reagin, Monospot, purified protein derivative, and chest radiograph as part of a routine diagnostic evaluation.[14]

We estimated the cost of these tests to be approximately $190. This cost, combined with the cost of an office visit ($45), results in a total cost of approximately $5.2 million for the estimated 22 000 ambulatory cat scratch disease patients per year. Assuming that the cost of one inpatient day in a community hospital ($760) with one physician visit ($40) is incurred for each day of hospitalization and that a surgeon's fee ($400) is billed to the 56% of the hospitalized patients who have lymph node procedures, the estimated cost for the 2000 patients hospitalized annually with cat scratch disease is $6.9 million. Thus the estimated total health care cost of cat scratch disease, in 1992 dollars, is over $12 million per year.



Note. CPHA records from 1983 through 1989 and NHDS records from 1979 through 1989 were analyzed.

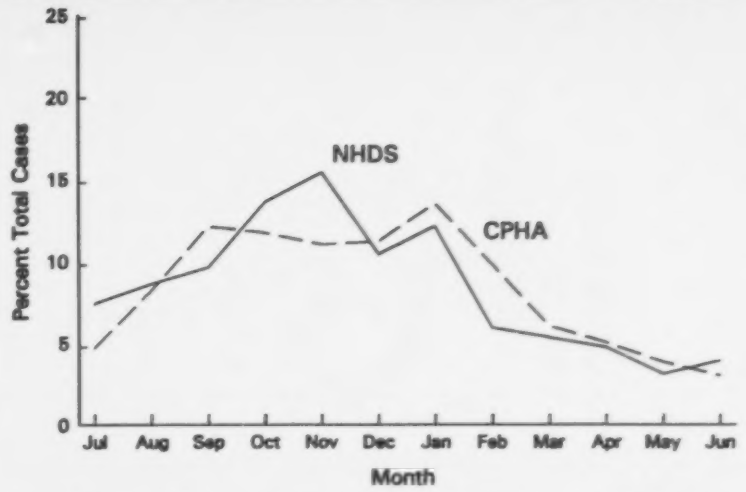
Note. CPHA records from 1983 through 1989 and NHDS records from 1979 through 1989 were analyzed.

FIGURE 3—Mean annual incidence of hospitalizations for cat scratch disease, estimated from National Hospital Discharge Survey (NHDS) and Commission on Professional and Hospital Activities (CPHA) data sets, by region.

Discussion

The rates of cat scratch disease reported here are consistent with previous estimates. The incidence of patients discharged from the hospital with a diagnosis of cat scratch disease, approximately 0.8 per 100 000 population, is similar to the incidence of 0.66 per 100 000 population reported by Carithers from his mail survey of hospitals discharging over 750 pediatric patients annually.[15] The estimate of overall incidence of the disease in ambulatory patients, 9.3 per 100 000 population, is just over 10 times the incidence in hospitalized



Note. CPHA records from 1983 through 1989 and NHDS records from 1979 through 1989 were analyzed.

FIGURE 4—Seasonal variation of hospitalizations for cat scratch disease, estimated from National Hospital Discharge Survey (NHDS) and Commission on Professional and Hospital Activities (CPHA) data sets.

patients. This estimate is similar in magnitude to the rate of 3.3 per 100 000 reported by Margileth[16] on the basis of outpatient studies in the metropolitan Washington, DC, area. Our estimate of the incidence of ambulatory cat scratch disease must be qualified, however, because it was extrapolated from very few cases; additional data, such as might be obtained from population-based surveillance, are needed for a more precise estimate.

The fall/winter peak in incidence noted in the CPHA and NHDS data sets is also congruous with previous reports.[15,17–19] The lack of a finding of seasonality in ambulatory cases is probably due to the small number of records analyzed.

Most investigators, such as Wlodaver and Vorse[20] and Carithers,[15] have found equal rates of disease for both sexes. Margileth,[17] however, in a review of 1252 patients, noted a significantly higher percentage of cases (58%) among males. The predominance of males found in this analysis was noted consistently in all three databases and is therefore likely to reflect a true difference rather than an artifact of data collection. Previous case series have not described the racial distribution of cat scratch disease case patients; however, we found a higher incidence in Whites than in Blacks. Additional investigation of risk factors for cat scratch disease may be useful to explore possible explanations for the gender and racial differences.

The incidence of hospitalizations for cat scratch disease was higher among children than adults, and approximately 54% of CPHA cases and 57% of NHDS cases were in persons 18 years of age or younger. However, children represented a markedly smaller percentage of total cases in both CPHA and NHDS data sets than that noted in most previous reports.[15,17,20,21] Carithers reported that 87% of his 1200 cat scratch disease patients were 18 or younger.[15] Similarly, Margileth, in a study of 1400 patients, noted that 83% were younger than 21,[17] and Wlodaver and Vorse, in a study of 23 patients, noted that 87% were 16 or younger.[20] These case series were reported by pediatricians and the patients were drawn primarily from ambulatory pediatric populations. Therefore, one explanation for the older age distribution found in our analysis is that previous studies were biased toward a younger age group because of the pediatric focus of the investigators. Disease in adults may have been underreported in those case series. This explanation is supported by the findings of Daniels and MacMurray, neither of whom were pediatricians, who described 160 cat scratch disease patients from 27 states and 8 foreign countries and found that only 66% were younger than 30 years of age.[22]

Another explanation for the older age distribution found in CPHA and NHDS records is that a disproportionate number of older patients with cat scratch disease are hospitalized, possibly because the disease is more severe in this age group. This is consistent with the finding of Margileth et al. that only 22% of cat scratch disease patients with severe, systemic disease were younger than 21,[12] compared with 87% of patients with uncomplicated cat scratch disease.[17]

Cat scratch disease is said to be one of the most common causes of chronic regional lymphadenopathy in children.[18,23] In this study, we were unable to compare the incidences of cat scratch disease and other causes of lymphadenopathy in children. However, although children with cat scratch disease accounted for only 3% of lymph node procedures performed on patients younger than 15 years, 16% of lymph node procedures in children aged 5 through 14 years discharged from September through January were in patients with cat scratch disease. It can be concluded from these data that cat scratch disease does cause a significant proportion of lymphadenopathy in children and that a substantial proportion of lymph node procedures performed on children during the fall and winter months are performed because of the disease.

We estimated the annual cost of outpatient evaluation of cat scratch disease to be $5.2 million and the cost of hospitalization to be $6.9 million, for an estimated combined annual cost of the disease of over $12 million. This is meant to be a minimum estimate. The actual cost is likely to be higher, since we did not attempt to include all of the health care costs that may be incurred by patients with cat scratch disease.

Although antibiotics have been suggested by several anecdotal reports to shorten the duration of illness,[23–27] no treatment requiring hospitalization has been proven beneficial to patients with cat scratch disease. Therefore, we assume that the majority of hospitalizations for cat scratch disease are for diagnostic purposes. If this is true, the availability of a reliable, noninvasive diagnostic test would reduce the need for hospitalization. Such a test would also decrease the number of additional tests required for the diagnostic evaluation of ambulatory patients. A recent report indicates that an indirect fluorescent antibody test for detection of humoral antibodies to *Rochalimaea henselae* may be useful for diagnosis of cat scratch disease.[2] Assuming that such a test would allow 90% of hospitalized patients to be treated as outpatients, that this test would be widely available, and that the cost of the test and the cost of

one office visit would be the only costs incurred for outpatients, a test costing $20 per patient would provide a yearly savings of at least $10 million.

This analysis was limited in many reports. Cat scratch disease represented a very small proportion of the total number of records included in the databases analyzed; therefore, the standard error was large and estimates made from these data are not expected to be precise. This problem is unavoidable when researchers seek to determine the incidence of a relatively uncommon disease from surveys that extrapolate from small samples. The diagnosis was obtained from coded records and was not standardized, so some of the patients included in the analysis may not have met standard diagnostic criteria for cat scratch disease. However, the seasonal variation, which was consistent with previous reports, provides some indication that cat scratch disease was correctly coded as a diagnosis for most records. Prospective, population-based surveillance may provide a more accurate estimate of incidence; however, we believe that the results of this analysis accurately reflect the general demographic characteristics of cat scratch disease.

In summary, we estimate that cat scratch disease affects approximately 22 000 persons and results in the hospitalization of about 2000 persons each year in the United States. Adults appear to represent a higher proportion of cases than previously reported, suggesting that cat scratch disease may be more common in adults than formerly recognized and that it should be considered in the differential diagnosis of chronic lymphadenopathy in adults as well as children. □

Estimates of the US Health Impact of Influenza

ABSTRACT

Objectives. Data from the Tecumseh Community Health Study were used to estimate excess morbidity owing to influenza, and results were compared with estimates made previously using different methodology for an Institute of Medicine report.

Methods. Study participants from Tecumseh, Michigan, were classified as infected or noninfected based on laboratory results. The excess numbers of respiratory illnesses, respiratory illness days, and bed and restricted activity days experienced by the infected compared with the noninfected were estimated.

Results. The number of excess influenza-related respiratory illnesses was lower than that estimated in the Institute of Medicine report, in which all illnesses of certain characteristics occurring during an influenza season were attributed to influenza. It is now estimated that the US population under 20 years of age experiences a yearly average of 13.8 to 16.0 million influenza-related excess respiratory illnesses; for older individuals, the yearly estimate is 4.1 to 4.4 million excess illnesses.

Conclusions. For public health purposes, estimates of excess morbidity as well as of total morbidity associated with influenza should be used in setting health priorities. (*Am J Public Health.* 1993;83:1712–1716)

Kevin M. Sullivan, PhD, MPH, MHA, Arnold S. Monto, MD, and Ira M. Longini, Jr, PhD

Introduction

Influenza has been classically characterized as "the last great uncontrolled plague of mankind" because of its perceived morbidity and mortality.[1(p373)] Estimates of the morbidity associated with influenza are problematic, however, because of the difficulty of distinguishing morbidity that is influenza specific from that associated with other respiratory pathogens circulating at the same time. Thus, assumptions must be made concerning the proportion of illnesses that are influenza and the duration of influenza outbreaks during which such illnesses occur. Because of these uncertainties, the Institute of Medicine's report on *New Vaccine Development*, when attempting to prioritize the impact of various infectious diseases, stated that there were very few data available on which to estimate the "disease burden" of influenza.[2(p344)]

Over a period of 11 years, the Tecumseh Community Health Study identified influenza infection and illness among individuals of all ages in an American population.[3] This study had features that allowed the impact of influenza to be estimated based on the weekly identification of the onset of respiratory illnesses and the determination of influenza infection by virus isolation and serology, all carried out over several seasons among approximately 750 participants. Methods are now applied to data from this study to estimate the most likely amount of excess morbidity associated with influenza. Results are compared with data used in the Institute of Medicine's determination of priorities for vaccine development.[2]

Methods

Population and Study Design

Descriptions of the population and study design of the Tecumseh study have been published previously and are summarized here.[4,5] There were two periods of investigation; the current study was restricted to the years 1976 to 1981. Starting in October 1976, households in Tecumseh, Mich, were randomly selected with no restrictions concerning household eligibility; the objective was to have approximately 1000 individuals (or 10% of the population) in the study. Households were retained indefinitely, with new households being recruited to replace those that dropped out of the study. A single family respondent was contacted weekly by telephone to obtain information on respiratory or enteric illnesses in household members. The collection instrument has been described previously, as have the case definitions.[6] For each acute illness reported, details were collected on symptoms, presence of fever, and other characteristics, such as the duration of the illness and the number of restricted activity days. Illnesses were followed weekly to their conclusion. When an illness was reported within 2 days of onset, specimens for microbiological isolation were collected.[7] Blood specimens were collected regularly every 6 months.

Serologic Tests and Virus Isolation

Laboratory methods that were used have been described in detail elsewhere.[5]

This paper was accepted June 28, 1993.

Infections were identified by detecting a rise in hemagglutination-inhibiting antibody titer from among a series of specimens collected from an individual. Viruses used as antigen were selected for their similarity to those in circulation. Antigens were either prepared from prototype strains at the University of Michigan or obtained from the Centers for Disease Control and Prevention. Type B antigens were ether treated to increase sensitivity.[8]

For isolation of the influenza virus, specimens were inoculated into two tubes of primary monkey kidney, incubated at 33°C, and observed over 3 weeks. Hemadsorbing isolates were typed by hemagglutination inhibition.

Definitions of Outcomes and Other Terms

A participant was considered to have been infected with influenza if one or both of the following had occurred: (1) a preseason titer of less than 1:8 and a postseason titer of at least 1:16, or a fourfold rise in influenza titer during the influenza season; (2) an isolation of influenza virus. The variables studied were as follows:

- The number of respiratory illnesses. Includes the total number of respiratory illnesses, as defined by Monto et al.,[6] in the study population that had an onset during the influenza season, and the excess number of respiratory illnesses, defined as the difference between the infected and the noninfected in the mean number of respiratory illnesses that had an onset during the influenza season.
- The number of days of illness due to respiratory illness. Includes the total number of days ill with a respiratory illness in the study population that had an onset during the influenza season, and the excess number of days ill, defined as the difference between the infected and the noninfected in the mean number of days ill with a respiratory illness that had an onset during the influenza season.
- The number of bed and restricted activity days owing to respiratory illness. Includes the total number of days in which the individual was ill and stayed in bed or in which the individual's usual activities (e.g., going to work or school) were interrupted (excluding days in bed), in either case because of a respiratory illness that had an onset during the influenza season; and the excess number of days in bed or restricted in activity, defined as the difference between the infected and noninfected in the mean number of bed or restricted activity days owing to a respiratory illness that had an onset during the influenza season.

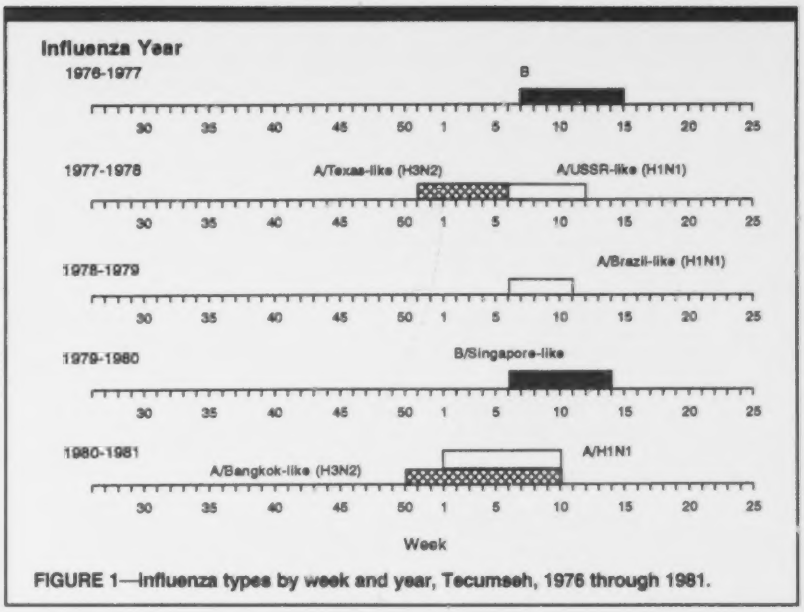

FIGURE 1—Influenza types by week and year, Tecumseh, 1976 through 1981.

The health effects of influenza were estimated by determining the excess frequency of the above health outcomes among the infected compared with the noninfected, and these results were compared with the overall frequency of the health outcomes during the influenza season. Other variables studied are as follows:

- Influenza season. The period of time in which a specific strain of influenza was isolated, during which there was an apparent excess of respiratory illnesses in the community.[5,9]
- Influenza year. The period of time in which influenza occurred, generally the last months of the calendar year and the first months of the following year. An influenza year may consist of more than one influenza season.

Age-Standardization and Sensitivity/Specificity Adjustments

All results were age adjusted using the 1980 US census data to standardize the age distribution throughout the study years. The age-standardized results were calculated for participants under 20 years of age and 20 years of age and older. The participants were divided into 5-year age groups for those under 20 years and older, but because there were few infections in certain age categories, some age groups were collapsed together. The age standardization for those under 20 years of age was based on three to four age groups, depending on the influenza season; for those 20 years of age and older, the standardization was based on two to five age groups.

Serologic tests for influenza are not 100% sensitive and specific.[1] Therefore, all results were provided with estimates adjusting for lower and higher levels of sensitivity and specificity: lower estimates were based on levels of 80% and 98%, respectively, and upper estimates were based on levels of 75% and 95%, respectively.

Results

Influenza infection occurred in Tecumseh in each of the study years. Influenza B was active in 2 years, type A(H1N1) in 3 years, and type A(H3N2) in 2 years (Figure 1). In 2 influenza years, both A(H3N2) and A(H1N1) circulated; in 1977 to 1978, the periods of circulation were separate, but in 1980 to 1981, the periods overlapped. It was thus impossible to attribute illness during the latter year to a single subtype, and so the 1980 to 1981 influenza year is omitted from the analyses of the health impact of influenza.

Table 1 shows the percentage of individuals infected in the different influenza seasons divided into the two age groups. In all years and for all influenza types and subtypes, the percentage of those infected was higher among the younger age group. The age-standardized percentage of participants infected per influenza season ranged from 5.4% to 20.4% (Table 1). For

all age groups, there was an age-standardized average of 182 influenza infections per year (including the 1980 to 1981 influenza year) per 1000 population.

Table 2 depicts the excess number of respiratory illnesses associated with influenza infection per 1000 population. For example, in the 1977 influenza B season, there were 81.2 excess respiratory illnesses observed per 1000 population under 20 years of age. The lower and upper estimates of the "true" excess (based on different sensitivity and specificity values for the laboratory tests) are 114.0 and 126.9, respectively. With one exception, there was greater excess of respiratory illnesses per 1000 population within the younger age group compared with those aged 20 years and older. The last column presents the total number of respiratory illnesses (both influenza and noninfluenza) with an onset during the influenza season. For the younger age group, this number is, on average, 6.4 times the lower estimated number of excess respiratory illnesses and 5.6 times the upper estimate; for the older age group, the corresponding values are 26.4 and 24.6 times, respectively (excluding the 1978 A(H1N1) season).

Table 3 depicts the excess number of days of respiratory illness associated with influenza infection. Again, with the exception of 1980, the youngest age groups had a greater number of excess days of respiratory illness per 1000, and there was variability from influenza season to influenza season. The last column presents the total number of days of respiratory illnesses with an onset during the influenza season. As on Table 2, the total number of days is much greater than the excess, especially for the older age group.

The excess number of bed and restricted activity days is shown in Table 4. In each influenza season, the younger age group experienced more of such days than the older age group, and there was variability from influenza season to influenza

TABLE 4—Age-Standardized[a] Excess Number of Bed or Restricted Activity Days due to Respiratory Illnesses Associated with Influenza, and Total Number of Bed or Restricted Activity Days due to Respiratory Illnesses per 1000 Population, Tecumseh, 1977 through 1980

season. The last column presents the total number of bed and restricted activity days; this number is, on average, 1.9 times the lower estimated number of excess bed and restricted activity days and 1.7 times the upper estimate within the younger age group; similar values for the older age group are 4.4 and 4.2, respectively.

The estimated 4-year average excess of respiratory illnesses, respiratory ill days, and bed and restricted activity days extrapolated to the 1980 US population are shown in Table 5. All estimates are in terms of millions. The impact of influenza in the United States has been previously estimated by the Institute of Medicine based on data from the Houston Family Study[2]; these data were based on respiratory illness estimates from studies in Houston[10–12] that cover similar years as the Tecumseh data. The Tecumseh data presented here are based on excess morbidity owing to influenza, whereas the Houston data are based on a total seasonal morbidity attributed to influenza. Table 5 presents the lower and upper estimates of the excess respiratory illnesses by age group based on the Tecumseh data; because of different age categories used in the Houston data, the number of influenza-associated illnesses in one age group (15.0 to 24.9 years) was evenly divided into the two age categories used in this study. Estimates from Houston for the two age groups are approximately 23.3 million for the younger age group and 24.4 million for the older age group (based on extrapolation of the Houston experience to the 1984 US population).

Discussion

To define influenza, this analysis used the excess number of total respiratory illnesses rather than a constellation of symptoms because the symptoms associated with influenza differ by age.[5] In all influenza seasons, individuals infected with the influenza virus had more respiratory illnesses, more days of respiratory illness, and more bed and restricted activity days than those not infected, but the excess was not homogeneous across the age groups.[13] The duration of the influenza seasons differed, and the selection of the beginning and ending of an influenza season was somewhat arbitrary. However, use of the difference (or excess) between infected and noninfected individuals should not be affected by the duration of the outbreak as long as the defined season covers the time of influenza activity.

In Tecumseh, use of the total number of health events (number of respiratory illnesses, days of respiratory illness, and bed and restricted activity days) would overestimate the excess number of health events associated with influenza infection, especially for the older age group. The more severe the outcome (from the number of days with respiratory illness to the number of severely ill [i.e., bed and restricted activity] days), the less the total number of events overestimated the excess number of events. It may be that, for the most severe health effects of influenza (such as hospitalization or mortality), the total number of events will overestimate the excess number even less, although this requires further study.

Reasons for the differences between the Tecumseh and Houston estimates appear mainly to relate to the different methods used to measure the outcomes. The Tecumseh data are based on excess respiratory illnesses whereas the Houston data are based on all respiratory illnesses occurring during an influenza season. It is possible that attributing all respiratory illnesses that occur during influenza seasons to influenza overestimates the disease burden of influenza. Another possible reason for the differences in these estimates could be presented by the following equation:

Total = Excess + Replacement,
where Total is the number of influenza illnesses,
Excess is the frequency of illnesses in the infected above the frequency in the noninfected, and
Replacement is when an influenza illness replaces a respiratory illness in those infected that would have been caused by another agent had influenza not occurred.

If influenza replaces other infectious agents among the infected during influenza outbreaks, then the total number of respiratory illnesses caused by influenza

would be greater than the excess alone. The excess number of respiratory illnesses caused by influenza provides a minimum estimate of the overall disease burden of influenza. Influenza infection may replace an infection by another respiratory agent,[5] or, if influenza infection is prevented, it may be replaced by another respiratory agent. From a cost-benefit point of view, measurement of the excess amount of the disease burden would be more valuable.

An unexpected finding was the severity of influenza B in the 1980 season among the adults. In terms of excess respiratory illnesses and excess days with a respiratory illness, this was the most severe season studied among the adults. These results are consistent, however, with the severity of this type B outbreak, which produced excess pneumonia and influenza deaths nationwide.[14]

The results presented are consistent with previous studies showing that influenza results in excess morbidity. One possible problem in these analyses is the potential for "cross-protective" effects between sequential A(H3N2) and A(H1N1) outbreaks in the same season.[15–17] Another is the sensitivity and specificity of the laboratory tests used, which would make the observed excess morbidity biased toward the null value of no difference between infected and noninfected individuals. With lower sensitivity and specificity estimates of 80% and 98%, respectively, and higher estimates of 75% and 95% respectively, the true health effects would be greater than the observed excess. The sensitivity and specificity of influenza laboratory tests most likely vary by influenza strain, age, and perhaps other factors. In this study, the proportion infected in each age group was treated as a fixed value. The estimates of the proportion infected is a random variable and is subject to sampling variability, which was not taken into account in these analyses.

The interpretation of the Tecumseh data extrapolated to the United States must be done with caution; this extrapolation was carried out principally to facilitate comparison with results presented in the Institute of Medicine's report, which used data derived from another community.[2] First, the data are based on fewer than 1000 participants per influenza season. Second, Tecumseh is located in a rural area in southeast Michigan, and it is not clear if the epidemiology of influenza in this community reflects the average experience in the United States. Third, it is difficult to compare estimates of total vs excess influenza morbidity. However, from a public health viewpoint, the latter would seem to be of greater importance. Thus, the estimates of the disease burden of influenza provided here may be useful for cost-benefit studies and policy purposes. □

The Risk of Measles, Mumps, and Varicella among Young Adults: A Serosurvey of US Navy and Marine Corps Recruits

ABSTRACT

Objectives. To assess the risk of epidemic transmission and to guide immunization policy, the seroprevalence of antibody to measles, mumps, and varicella was determined in a group of young adults.

Methods. A cross-sectional study of 1533 US Navy and Marine Corps recruits was conducted in June 1989. Antibody status was determined with commercially available enzyme-linked immunosorbent assays.

Results. Direct sex and race adjustment to the 15- to 29-year-old US population resulted in seronegativity rates of 17.8% for measles, 12.3% for mumps, and 6.7% for varicella. Measles and mumps seronegativity rates were higher among Whites whereas varicella seronegativity was higher among non-Whites. Recruits enlisting from outside the 50 US states, especially those from island territories, were more likely to lack varicella antibody. The sensitivity of a positive history of vaccination or disease in predicting antibody status was less than 90% for all diseases.

Conclusions. These results suggest a continued potential for epidemics, especially of measles, and the need for mandatory immunization policies. Immigrants to the United States, especially those from island territories, may be a high-risk group that could benefit from varicella vaccination. (*Am J Public Health.* 1993; 83:1717–1720)

Introduction

Despite great progress in the United States over the last several decades in controlling vaccine-preventable illnesses,[1,2] recent increases in the incidence of measles and mumps—including epidemics—have occurred,[3,4] especially among inner-city children and young adult populations.[5–13] These viral illnesses also continue to have considerable military importance.[14–18] In addition, varicella, a serious illness in adults,[19–21] may also be increasing in incidence, particularly in military populations.[22]

Recruits enter the service from all areas of the country and most are between 17 and 19 years old, an age group at high risk in the civilian setting for measles, mumps, and varicella. Because these viral illnesses may have a great impact on health, training time, and overall military readiness, especially in the recruit setting, and because their importance is increasing in the civilian population, a serosurvey was conducted to guide immunization policy. In addition, demographic factors and other information related to individuals' previous disease and vaccination history were evaluated as potential predictors of antibody status.

Methods

This study was conducted in June 1989 at the three US Navy (Great Lakes, Ill; Orlando, Fla; San Diego, Calif) and the two US Marine Corps (Parris Island, SC; San Diego, Calif) recruit training centers. Four consecutive companies/platoons at each location were enrolled in the study. Those recruits who gave informed consent completed a short questionnaire and donated an extra tube of blood.

Blood samples were obtained 1 to 4 days after the recruits' arrival at the training center and before the administration of immunizations. Serum samples were tested for measles, mumps, and varicella antibodies using commercially available enzyme-linked immunosorbent assay (ELISA) tests (MEASLESTAT, MUMPSTAT, and VARICELISA II from Whittaker Bioproducts, Walkersville, Md). To assess interrater reliability, 150 randomly selected samples were retested by the manufacturer. The kappa value for varicella retesting was 0.96, and no further retesting was performed. Because the kappa values for measles and mumps were lower (0.83 and 0.77, respectively), the manufacturer retested all samples for these two antibodies in the laboratory, and the manufacturer's results were used in the analysis. Samples were initially tested for rubella antibody as well, but extremely high seronegativity rates suggested technical difficulties with the procedure, and insufficient serum was available to allow retesting of samples. Therefore, no rubella results are presented. All testing was done without knowledge of the subjects' prior disease or vaccination history.

The self-completed questionnaire included demographic variables and information on state of birth, elementary

Note. Age was missing for 9 males and 1 female, education for 2 males, and area of enlistment for 5 subjects.

school entry, and military enlistment. Subjects were asked to recall their history of having had each of the individual diseases and vaccinations, with four possible responses: (1) yes, definitely; (2) yes, probably; (3) no, definitely not; and (4) I don't know.

The Centers for Disease Control and Prevention reports of school entry immunization laws for each state were available for 1970 to 1977, 1979 to 1980, 1983, and 1985 to 1990. These reports were used to determine the year-specific state school entry immunization laws for each recruit.

Statistical analyses were conducted with EGRET statistical software (SERC, Inc, Seattle, Wash) on a microcomputer. To compare the proportion of recruits who were seronegative, logistic regression for the continuous variable of age, the Mantel-Haenszel chi-square test for trend in education, and the likelihood ratio chi-square for other variables were used. Adjustment for potential confounders in the association between race and seronegativity was performed using logistic regression models.

The proportion of seropositive recruits who reported a positive history of disease or vaccination was defined as the sensitivity of the historical information, and the proportion of seronegative recruits who did not report prior disease or vaccination was defined as the specificity. Positive predictive value was defined as the proportion of history-positive recruits who were seropositive, and the negative predictive value was defined as the proportion of history-negative recruits who were seronegative.

Results

Of the 1568 recruits assigned to the selected companies, 1533 (98%) gave informed consent and participated in the study. Among the 1442 subjects enlisting from one of 48 US states, 90% were male, 74% were aged 17 to 19, 70% were White, 18% were Black, and 9% were Hispanic. Seronegativity rates and 95% confidence intervals were as follows: measles, 19.0% (17.0, 21.0); mumps, 11.7% (9.6, 13.8); and varicella, 8.2% (6.8, 9.6). Direct sex and race adjustment to the 1980 US 15- to 29-year-old population resulted in estimated national seronegativity rates of 17.8% for measles, 12.3% for mumps, and 6.7% for varicella. Seronegativity to measles and mumps was not highly correlated, with only 2.8% seronegative for both.

Men were more likely to be seronegative for all three viruses, and results are presented separately for men and women (Table 1). Younger male recruits were more likely than older ones to be seronegative for measles and mumps ($P > .05$), but older female recruits were more likely than younger ones to be seronegative for mumps ($P < .05$). Age was not associated with varicella antibody status for either men or women. Higher educational level was associated only with lower mumps seronegativity in men ($P < .01$). Among both men and women, Whites were more likely to be seronegative for measles and mumps while non-Whites were much more likely to be seronegative for varicella antibody ($P < .05$ for men). The association between race and antibody status for all three viruses persisted after controlling for age, sex, and educational level.

Recruits in this study had enlisted from 48 of the 50 states, and although there was wide variation in seronegativity between states, no clear geographic trends were evident. Recruits whose state of enlistment had full mumps immunization entry laws (kindergarten through grade 12) were slightly less likely to be seronegative for mumps (9.8%) compared with other subjects (13%). No other associations between state immunization laws and measles or mumps antibody status were present, even when those recruits who reported the same state of birth, elementary school entry, and military enlistment were analyzed separately.

Eighty-four recruits (5%) enlisted from outside the United States. Except for those recruits enlisting directly from the Republic of the Philippines, most of whom receive measles/rubella immunization as part of their processing before arrival in the United States, their rates of measles

and mumps seronegativity were similar to those of US enlistees. However, more than 20% of recruits enlisting from outside the United States, including 3 of 3 from the Canal Zone, 2 of 3 from Puerto Rico, and 6 of 23 enlisting from the Republic of the Philippines, were varicella seronegative.

Combining recruits who reported a positive history of disease *or* vaccination, the sensitivity of a "definite" history in identifying seropositive recruits was less than 35% for both measles and mumps (Table 2), whereas the sensitivity of a definite history of varicella disease was 75%. Definite *or* "probable" histories of disease or vaccination doubled the sensitivity for measles and mumps, and increased the sensitivity of varicella disease history to 86%. Corresponding specificities were similar, ranging from 35% to 72% for measles and mumps, to 66% to 75% for varicella. The sensitivity of vaccine history was generally better than the disease history.

The negative predictive value was lower for mumps than for measles or varicella. On the other hand, the positive predictive value of a history of varicella was over 95%. However, almost all recruits gave a positive history of varicella, including more than 20% of those lacking the varicella antibody.

TABLE 2—The Ability of Undocumented History of Disease or Vaccination to Predict Serum Antibody Status to Measles, Mumps, and Varicella

Self-Reported Historical Information	No. with Positive History/Total	Sensitivity[a]	Specificity[b]	PV +[c]	PV –[d]
Definitely had measles disease or vaccine	470/1434	33.5	70.4	82.8	20.0
Definitely or probably had measles disease or vaccine	935/1434	66.2	35.0	81.0	19.2
Definitely had mumps disease or vaccine	472/1436	33.5	72.1	90.0	12.7
Definitely or probably had mumps disease or vaccine	959/1436	67.5	38.5	89.2	13.6
Definitely had varicella disease	421/1437	74.8	75.2	97.1	20.9
Definitely or probably had varicella disease	1171/1437	85.7	65.8	98.6	28.9

Note. Individual disease/vaccine totals fall below sample total because of missing values.
[a]Sensitivity is the proportion of antibody-positive subjects who gave a positive history.
[b]Specificity is the proportion of antibody-negative subjects who gave a negative history.
[c]PV+ is the positive predictive value, or the proportion of history-positive subjects who were antibody positive.
[d]PV– is the negative predictive value, or the proportion of history-negative subjects who were antibody negative.

Discussion

Based on commercially available ELISA tests, nearly one fifth of the 1533 recruits in this study lacked antibody to measles, 12% lacked antibody to mumps, and 9% were seronegative for varicella antibody. Direct adjustment to the 1980 US 15- to 29-year-old population yielded similar results. If seronegativity correlates with susceptibility, these results suggest the potential for continued epidemic transmission of measles in young adult populations. However, a routine two-dose schedule of the measles/mumps/rubella vaccination, as has been recommended,[23,24] should considerably reduce this potential.

The direct US adjusted measles seronegativity rate (17.8%) observed in this study was higher than expected, based on several serosurveys in the past 2 decades,[15,25,26] but was comparable to the rate of 20.7% in a recent study of US Army recruits.[27] Fewer previous mumps serosurveys have been reported,[28] but the adjusted mumps seronegativity rate of 12.3% in this study was comparable to that found in the most recent US Army recruit survey.[27] The 6.7% adjusted varicella seronegativity rate was similar to that found in two recent studies[27,29] but lower than that found in another.[26]

The lower seronegativity rate for measles and mumps among older male subjects in this study probably reflects increased natural infection during childhood. Among the group born before 1964, vaccination was not widespread when most subjects entered elementary school. The lack of association between age and varicella seronegativity rates observed in this study suggests no decrease in natural infection rates in recent years.

Whites were more likely to be seronegative to both measles and mumps and less likely to be seronegative to varicella, even after adjustment for age, sex, and education. This finding may reflect lower rates of natural measles and mumps infection among Whites or higher rates of waning vaccine-induced antibody levels. The associations between race and varicella seronegativity and between sex and seronegativity to all three viruses may reflect unknown sociocultural differences in patterns of natural infection or vaccination. Recruits enlisting from outside the 50 US states, especially those from island nations or territories, were much more likely to be seronegative for varicella antibody. This supports the previous epidemiological observations of an island phenomenon.[21,30] Especially in the health care and military recruit environments, foreign-born individuals may represent a high-risk group that could benefit from a varicella vaccine.[31]

The specificity of historical information of measles disease or vaccination was higher in this study than in a prior study of medical students.[26] However, using this historical information to determine which recruits should be vaccinated or receive antibody tests would not effectively reduce the proportion remaining seronegative to below 8%. Both the sensitivity and specificity of a history of varicella in this study were generally higher than in a previous study.[26] Most recruits, however, reported a positive history of disease, and more than 20% of seronegative recruits would be missed if such a screening question were used to determine who would receive varicella immunization. The lower negative predictive value for mumps compared with that for measles and varicella is probably owing to the fact that mumps infection is often subclinical.

Several factors need to be considered when interpreting the results of this serosurvey. Although the ELISA tests used here appear to be as good as previous antibody tests when compared to a gold standard,[32–38] they may not correlate with true susceptibility to these illnesses. However, given the evidence for the role of waning vaccine-induced antibody levels in recent outbreaks of measles,[39,40] a less sensitive test may be desirable if it is being used to decide who gets immunized in the recruit setting. Although the true number of young adults currently susceptible to these illnesses may be considerably lower than this serosurvey suggests, these results may be predictive of the future potential for epidemics, especially if the intensity of exposure increases, because

vaccine-induced antibody titers may continue to wane.

Subjects in this study came from most areas of the United States, but whether they are representative of the civilian population with respect to their infection and vaccination experiences and associated risk factors is unknown. This was a cross-sectional study done over a short period, and further studies of these subjects and cross-sectional studies over time will be important in monitoring seroprevalence trends.

The high rates of seronegativity among US recruits suggest the continued potential for epidemics of these illnesses and the need for continued effective immunization programs in both the civilian and military setting. In the recruit training center environment, historical information on previous disease and vaccination history would not be an effective guide in determining who should be immunized upon entry into the US military. □

Multiethnic Variations in the Pregnancy Outcomes of Military Dependents

ABSTRACT

Objectives. We examined the pregnancy outcomes of three ethnic groups: African-American Blacks, non-Hispanic Whites, and Filipinos. In an attempt to reduce ethnic dissimilarities in parental employment and access to health care, this investigation compared the single-live-birth outcomes of married, adult women who resided in the state of Hawaii and who indicated that their spouse was on active-duty status in the US military.

Methods. The data for this study were obtained from the 1979–1989 Hawaii vital-record file that provides linked live birth–infant death information. Multiple logistic regression was used to calculate odds ratios for the independent effects of maternal factors on low birthweight and neonatal mortality.

Results. Significant differences in maternal age, maternal education, paternal education, parity, hospital of delivery, and use of prenatal care were observed among the ethnic groups. The results of a logistic regression analysis of low birthweight indicated significantly higher risks for Filipinos and Blacks compared with Whites. For very low birthweight, only an increased risk for Blacks was observed. No ethnic differences in neonatal mortality were found.

Conclusions. This investigation revealed more comparable infant mortality experiences among the ethnic groups in spite of persistent birthweight differences. (*Am J Public Health.* 1993;83:1721–1725)

Introduction

Although infant mortality rates have declined markedly during the last century in the United States, ethnic disparities in infant mortality and related measures of pregnancy outcome persist; with respect to some ethnic comparisons, notably between White and Black, these disparities have increased.[1] The factors that underlie these ethnic variations have become an important area of research in the public health, social science, and medical fields. However, in spite of ongoing programmatic and policy efforts to close the gap in measures of pregnancy outcome among ethnic groups, there is reason for serious concern that these disparities will extend to another generation of infants.

Numerous studies have revealed that these ethnic variations in pregnancy outcome can be partially explained by socioeconomic factors, demographic factors, extent of prenatal-care utilization, and conditions associated with medical risk.[1–19] However, many of the observed ethnic differences in pregnancy outcomes remain unexplained. Controlling for disparities in employment status, living conditions, and access to and use of health care resources represents a formidable challenge to studies of ethnic variation in pregnancy outcomes. In investigations using data from vital records, maternal education, age, and marital status are typically the only variables available to indicate socioeconomic status and to adjust for disparities in socioeconomic status among ethnic populations. Although indices of prenatal-care utilization have been used to control for ethnic variations in adequacy of prenatal care, these indices do not consider the influences of differences in the content and quality of prenatal care received by various ethnic groups.[8,20,21] Finally, much of the US scientific literature on ethnic differences in pregnancy outcomes has been centered on the comparison of Black and White populations. Only a few studies have considered multiple ethnic groups or have further attempted to control for content and quality of prenatal care.[5,22] Notwithstanding the appreciable and disturbing contrasts provided by the prevailing research focus on Black–White biethnic differences, the inclusion of other ethnic groups in future investigations may offer new insights.

In this study, we examine the pregnancy outcomes of three ethnic groups: African-American Blacks, non-Hispanic Whites, and Filipinos. In an attempt to reduce ethnic dissimilarities in parental employment, general living environment, and access to health care, this investigation compares the single-live-birth outcomes of married, adult women who resided in the state of Hawaii and who indicated that the father of the infant had an active-duty US military status. Previous comparisons of ethnic variation in pregnancy outcome among military populations have been largely limited to Black and White populations.[15,18,19,23]

The investigation of data from the state of Hawaii offers several unique ad-

TABLE 1—Parental and Prenatal-Care Characteristics, by Ethnicity of Mother

Characteristic	Ethnicity of Mother, %		
	White (n = 24 674)	Filipino (n = 4521)	Black (n = 4617)
≥35 years of age	3.04	7.10	1.84
<12 years of education (mother)	8.20	17.02	6.29
Primipara	46.29	37.56	37.58
High parity for age[a]	0.52	0.77	0.82
>12 years of education (father)	39.68	41.77	28.95
Military hospital delivery	82.46	78.50	86.51
First-trimester prenatal care	81.58	75.38	77.39
Inadequate or no prenatal care[b]	3.23	5.82	5.24

Note. Data are for single live births to adult, married, military-dependent mothers residing in Hawaii 1979 through 1989. *P* value (chi-square test) for all characteristics is $P < .01$.
[a]High parity for age: for women 18–21 years, three or more births; for women 22–24 years, four or more births; for women 25+ years, five or more births.
[b]Institute of Medicine Index of Adequacy of Prenatal Care.[20]

TABLE 2—Pregnancy Outcomes, by Ethnicity of Mother

Outcome	Ethnicity of Mother			
	White	Filipino	Black	*P*
Very preterm,[a] %	1.10	1.59	2.62	<.01
Preterm,[b] %	6.45	10.17	11.09	<.01
Very low birthweight,[c] %	0.66	0.86	1.58	<.01
Low birthweight,[d] %	4.66	6.44	8.39	<.01
Heavy birthweight,[e] %	5.61	2.01	2.08	<.01
Low birthweight and preterm,[f] %	2.49	3.35	4.96	<.01
Low birthweight and term,[g] %	2.11	2.92	3.27	<.01
Neonatal mortality rate	4.7	5.3	6.3	.36
Postneonatal mortality rate	2.1	2.2	3.5	.19
Infant mortality rate	6.8	7.5	9.7	.09
Mean birthweight (g)	3432	3229	3206	<.01
Mean gestation (wk)	39.86	39.07	39.08	<.01

Note. Data are for single live births to adult married, military-dependent mothers residing in Hawaii 1979 through 1989.
[a]Less than 33 weeks of gestation.
[b]Less than 37 weeks of gestation.
[c]Less than 1500 g.
[d]Less than 2500 g.
[e]Greater than or equal to 4250 g.
[f]Less than 2500 g and <37 weeks of gestation.
[g]Less than 2500 g and ≥37 weeks of gestation.

vantages. Hawaii has a multiethnic culture without a single predominant ethnic group. It has a relatively stable and temperate climate. There is a sizable US military population that has access to a large military health care center (Tripler Army Medical Center), where perinatal health care with presumably consistent content and quality is available to eligible recipients. Although these features do not provide precise control for all disparities in living conditions, employment status, racism, environment, and access to and use of health care resources, they offer modest advantages in an effort to reduce the influence of these potential confounders.

Methods

The data for this study were obtained from the 1979–1989 Hawaii vital-record file that provides linked live birth–infant death information. This file contains coded information from all certificates of live birth from the study period and appended information from the death certificates of those infants who died during the first year of life. Although the state of Hawaii has reciprocal vital-record agreements with other US states, no studies were located that investigated whether an appreciable underreporting of out-of-state infant deaths occurs or whether underreporting varies by the military status and ethnicity of the mother. Single live births to mothers residing in Hawaii were selected for analysis based on the following additional criteria: (1) the mother was married, 18 years of age or older, and non-Hispanic White, Black, or Filipino, based on the stated race of the mother on the birth certificate; and (2) the birth certificate indicated that the father was on active-duty status in the US military.

The χ^2 test and *t* test were used to test for significant bivariate ethnic differences in maternal characteristics and pregnancy outcomes. Multiple logistic regression was used to calculate odds ratios for the independent effects of maternal factors on low birthweight and neonatal mortality.

Gestational age in completed weeks was calculated as the interval between the date of last normal menses and the date of birth, with the use of recommended procedures for imputing values when the day of last normal menses is unknown.[24] Adequacy of prenatal-care utilization was determined based on a modification of the Institute of Medicine index.[20]

Results

Maternal and paternal sociodemographic, prenatal-care utilization, and hospital utilization characteristics are shown by ethnic group in Table 1. Significant ethnic differences were observed for every factor examined. Compared with Black and White mothers, Filipino mothers were more likely to be 35 years of age and older, were less likely to initiate prenatal care in the first trimester, and were more likely to have less than 12 years of education. Lower percentages of inadequate prenatal-care utilization and high parity for age were found for White mothers. The lowest proportion of fathers with more than 12 years of education was observed for Blacks.

Table 2 presents pregnancy outcome data by ethnicity. Significant ethnic differences were apparent for all measures of birthweight and gestational age. The mean birthweights and gestational ages of Black and Filipino infants were similar, but these were approximately 200 g and three quarters of a week less than the mean birthweight and gestational age, respectively, of White infants. White infants had the lowest percentages of low birthweight and preterm delivery. Black and Filipino infants had similar percentages of preterm delivery, but Black infants had markedly higher percentages of very low birthweight and very preterm delivery.

No significant ethnic differences in neonatal, postneonatal, and infant mortal-

ity rates were observed. White infants had the lowest rates and Black infants had the highest rates of neonatal, postneonatal, and infant mortality.

Birthweight percent distributions by maternal ethnic group are provided in Figure 1. The Black and Filipino distributions were similarly positioned on the birthweight axis but shifted relative to the White distribution toward the lower end of the birthweight scale. The low-birthweight portion of the distribution is highlighted in the left-hand portion of the figure. Below 1750 g, the Filipino and White distributions are more similar to each other, with the Black distribution having a relatively greater percentage of infants weighing less than 1500 g (see Table 2). Between 1750 and 2500 g, the birthweight percent distributions for Blacks and Filipinos are more similar, with lower proportions observed for Whites. Ethnic variations were observed in the gestational-age distribution and followed patterns similar to those observed for birthweight.

The results of the logistic regression analyses, focusing on very low and low birthweights, are presented in Table 3. The same independent characteristics considered in each analysis included measures of maternal age, parity, maternal and paternal education, prenatal-care utilization, hospital of delivery, and ethnicity. In both analyses, older maternal age (≥35 years), primiparity, inadequate prenatal care, and a nonmilitary hospital of delivery were identified as significant risk factors. A father with more than 12 years of education was found to be a protective factor, reducing the risk of these outcomes. Both Filipino and Black maternal ethnicity increased the risk of low birthweight compared with the risk for Whites. For very low birthweight, the Black odds ratio (2.48, confidence interval [CI] = 1.87, 3.28) was significantly higher than that for Whites, but the Filipino odds ratio (1.25, CI = 0.88, 1.78) was not significantly different than that for the White reference group.

Table 4 presents the results of logistic regression analyses that focused on neonatal and infant mortality. The same independent variables used in the preceding analyses (Table 3) were considered. Primiparity, inadequate prenatal care, and a nonmilitary hospital of delivery increased the risk of both mortality measures, whereas a father with more than 12 years of education decreased the risk. Maternal age of 35 years or more was found to increase the risk of infant mortality. Maternal ethnicity was not found to significantly increase the risk of neonatal mortality. A significantly higher risk of infant mortality was identified only for Black mothers.

TABLE 3—Results of Logistic Regression Analysis of Low Birthweight and Preterm Delivery

Risk Factor	Low Birthweight			Very Low Birthweight		
	Odds Ratio	95% CI	*P*	Odds Ratio	95% CI	*P*
≥35 years of age	1.50	1.18, 1.90	<.01	2.16	1.26, 3.69	<.01
Primipara	1.41	1.28, 1.56	<.01	1.70	1.33, 2.17	<.01
High parity for age[a]	1.86	1.16, 2.99	.01	2.47	0.89, 6.86	.08
<12 years of education (mother)	1.17	1.00, 1.37	.06	0.88	0.56, 1.37	.56
>12 years of education (father)	0.85	0.77, 0.94	<.01	0.71	0.55, 0.93	.01
Inadequate or no prenatal care[b]	1.78	1.46, 2.16	<.01	2.19	1.42, 3.36	<.01
Nonmilitary hospital delivery	1.28	1.14, 1.44	<.01	1.79	1.36, 2.35	<.01
Filipino mother	1.37	1.20, 1.57	<.01	1.25	0.88, 1.78	.22
Black mother	1.91	1.69, 2.15	<.01	2.48	1.87, 3.28	<.01

Note. Data are for single live births to adult, married, military-dependent mothers residing in Hawaii 1979 through 1989.
[a]High parity for age: for women 18–21 years, three or more births; for women 22–24 years, four or more births; for women 25+ years, five or more births.
[b]Institute of Medicine Index of Adequacy of Prenatal Care.[20]

To explore whether these observed ethnic patterns in the risk of mortality varied by birthweight, the study population was divided into low-birthweight (<2500 g) and normal-birthweight (≥2500 g) groups. Infant mortality was again investigated for each birthweight group by use of logistic regression that contained the same independent variables indicated in Table 4. No significant differences in the risk of infant mortality were found among the three ethnic groups. For low-birthweight infants, the odds ratio for the Black group was 1.07 (CI = 0.70, 1.64), and the odds ratio for the Filipino group was 0.86 (CI = 0.53, 1.41). For normal-birthweight infants, the odds ratio for Blacks was 0.84 (CI = 0.45, 1.56), and the odds ratio for Filipinos was 0.91 (CI = 0.49, 1.70).

The six categories proposed by Baruffi et al. (perinatal-related conditions, injuries, infections, sudden infant death syndrome, congenital anomalies, other)[25] were used to examine causes of infant death for each maternal ethnic group. The small number of cases in each category precluded an examination of significant differences; however, higher proportions of deaths due to sudden infant death syndrome and perinatal-related conditions were observed for Blacks.

Percentages of low and very low birthweights, percentages of preterm and very preterm deliveries, and neonatal and infant mortality rates were examined

TABLE 4—Results of Logistic Regression Analysis of Neonatal and Infant Mortality

Risk Factor	Neonatal Mortality			Infant Mortality		
	Odds Ratio	95% CI	P	Odds Ratio	95% CI	P

[d]Less than 2500 g.

for single live births to non–military-dependent, adult, married mothers residing in Hawaii (Table 5). These measures of birth outcomes were calculated for a cursory comparison with those of the military-dependent study population (Table 2). For Whites, each of the above six measures was higher for the military group compared with the nonmilitary population. For Blacks, a relatively small nonmilitary resident population in Hawaii, the reverse was observed, with the military group demonstrating lower percentages and rates than the nonmilitary population. For Filipinos, the military group had lower percentages of preterm deliveries, very preterm deliveries, and low birthweights but had higher neonatal and infant mortality rates.

Discussion

This study population was selected to examine multiethnic differences in pregnancy outcomes among adult, married women whose spouses were members of the US military. These women were presumably not living in extreme poverty and had similar availability of and access to comparable prenatal-care and hospital delivery services. Using the year 2000 target objectives for US health status as a reference standard, the measures of pregnancy outcome for this study population were relatively good and in most cases were near or below the year 2000 target objectives for the respective ethnic groups.[26] (No target objectives have been published for Filipinos.) Nevertheless, notable ethnic disparities in some of the indicators remain.

After controlling for available socioeconomic characteristics, the risk of low birthweight for infants of Black mothers was almost twice that for infants of White mothers, approximating the Black to White ratio of low-birthweight percentages found in many other studies.[1,5,8,22] Compared with infants of Black mothers, the infants of Filipino mothers were shown to have a lower percentage of low birthweight, although their mean birthweight was comparable to that of Black infants. Filipino mothers initiated contact with and utilized prenatal-care services slightly less adequately than Black mothers. Within low- and normal-birthweight categories, no significant differences were found among the three ethnic groups in infant mortality, suggesting that the observed ethnic variation in overall mortality rates was mainly a function of birthweight distribution differences. In particular, the main difference between the Filipino and Black groups was the strikingly excessive proportion of infants with very low birthweight born to Black mothers.

Nativity status of the mother has been identified by several studies as being associated with pregnancy outcomes.[27–29] In this study, a large proportion of Filipino mothers were foreign-born, whereas the vast majority of White and Black mothers were US-born. A previous investigation of the effect of nativity status on the outcomes of Filipino births in Hawaii indicated few differences between US- and Philippines-born women residing in Hawaii.[30] Due to the high correlation between nativity status and Filipino ethnicity, this variable was excluded from this analysis.

In spite of the availability of and access to health care facilities, the proportion of mothers in the study population who initiated prenatal care in the first trimester did not reach the year 2000 target objective of 90%. Other studies have noted decreased utilization of prenatal-care services among military personnel and have commented that the reduction of financial barriers alone may not be sufficient to stimulate increased utilization of prenatal-care services.[15]

The finding of a higher risk of low birthweight and mortality among infants delivered at a nonmilitary hospital was unexpected. One explanation for these results is that some high-risk cases may have been delivered at civilian tertiary-care centers. This possibility was investigated. It was found that the majority of the nonmilitary hospital deliveries did occur at another tertiary-care center. Unfortunately, these data are insufficient to document that these cases represented high-risk transfers.

Paternal education in excess of 12 years was found to have a protective effect on low birthweight and infant mortality. Paternal education has less frequently been considered in pregnancy outcomes investigations, and among married

women, it may provide a useful additional indicator of socioeconomic status. In this particular population, paternal education may in part reflect military rank with accompanying variations in levels of pay, housing allowance, and social status.

In this study, no measures of maternal smoking, height, weight, and weight gain during pregnancy were available for consideration. Blacks have been reported to smoke less than Whites, and this observation has also been made in military populations.[14,19,21] Variations in maternal height and weight, which have been found to be related to infant birthweight, are likely among these three ethnic groups.[31] Although no information could be identified to suggest how these measures would vary among ethnic groups in the US military population, they constitute an area for further review.

Although subordinate to the primary focus of this paper, ethnic-specific differences in pregnancy outcome measures were observed between the military and nonmilitary resident populations of adult, married mothers (Tables 2 and 5). These cursory findings, suggesting that the White military group may have worse outcomes and the Black military group may have better outcomes than their nonmilitary counterparts, indicate the need for further study of ethnic-specific differences in pregnancy outcomes between military and nonmilitary populations in terms of socioeconomic and employment factors; parental risk characteristics; and sources, management, and utilization of perinatal health care services.

Overall, the findings of this study of ethnic variation in pregnancy outcomes underscore the complex and poorly understood nature of this phenomenon. Although ethnic differences in low-birthweight and very low birthweight percentages persisted at significant levels, the neonatal mortality rates among ethnic groups approached greater comparability. These observations raise further questions regarding the validity of low birthweight as a multiethnic indicator of mortality risk.[32] This issue continues to emerge and has been highlighted by recent disclosures of information on Asian birthweight distributions and infant mortality rates.[33] However, theories that propose the possibility of normal ethnic variations in mean birthweight and gestational age do not explain the excess percentages of very preterm deliveries and very low birthweight found among infants born to Black mothers in this study. The prevention of very preterm birth in Black populations remains a separate and demanding issue, which must be addressed to reduce the ethnic gap in pregnancy outcome indicators found in the United States. □

Custody of Cocaine-Exposed Newborns: Determinants of Discharge Decisions

Daniel R. Neuspiel, MD, MPH, Terry Martin Zingman, MPH, Virginia H. Templeton, BA, Paula DiStabile, MSN, JD, and Ernest Drucker, PhD

ABSTRACT

Objectives. Maternal cocaine use is a leading grounds for newborn foster placement. This study was initiated to investigate the factors that predict custody status of infants born to substance-abusing women.

Methods. A retrospective cohort design was used to study the correlates of discharge custody decisions for 99 consecutive infants testing positive for cocaine in a public hospital.

Results. The population was 49% Black, 40% Hispanic, and 11% other or unknown. Custody at discharge was to mothers (38%), other family members (25%), or agency foster care (36%). Placement outside the family was greater when mothers had prior child welfare records, in Blacks vs others, with no prenatal care, and when mothers were younger at their first delivery or older at the index birth. Denial of custody to the mother was higher with prior child welfare involvement, in Blacks, and when the mother did not live in her own home. Both models also controlled for parity, child sex, and birthweight.

Conclusions. Earlier involvement with child welfare authorities, race, and other factors predict continued separation of mothers and children at newborn discharge, suggesting the need to reexamine current policies and practices. (*Am J Public Health.* 1993;83:1726–1729)

Introduction

Substance use in pregnancy is a major social and medical problem, affecting the woman, her new child, and other family members.[1] Because of concern about the ability of drug-using women to care adequately for their children, child protection authorities in many jurisdictions have acted to separate these mothers from their infants after birth.[2–4]

In the state of New York, child abuse and neglect laws have been applied in cases in which newborn urine assays have shown evidence of illicit drugs, particularly cocaine or its metabolites. Local child welfare authorities in New York City are delegated the authority to investigate such cases and to decide temporary placement at the newborn's hospital discharge. These decisions are made after input by hospital social work staff and assessment of the family and home environment. Some of these infants are discharged to their mothers or other family members, and some are discharged to foster care agencies for nonfamily placement. On occasion, mothers may voluntarily agree to have their infant placed in foster care. Maternal cocaine use has become the leading grounds for newborn foster placement in New York City. Substance use also contributed to the 29% nationwide increase in foster care between 1986 and 1989.[5]

In New York State, immediate newborn discharge placement is followed by a family court determination of custody and may not represent the long-term location of custody. However, separation of mother and child at this time may have a lasting impact on the mother–infant relationship.[6] Prior studies have not reported on factors influencing the decision to send a cocaine-exposed newborn home with his or her mother or to foster care placement with a relative or agency. Also, no previous research has studied the predictors of foster care placement of infants of substance-abusing mothers. Although child welfare policy calls for reunifying separated mothers and children, little information exists on the success of current policies in promoting family cohesion. This study was performed to explore the determinants of newborn discharge custody placement in a cohort of cocaine-exposed infants.

Methods

Subjects

This investigation used a retrospective cohort design. The study sample included all newborns testing positive for cocaine or its metabolite benzoylecgonine by enzyme-immunoassay-technique urine assay[7] from July 1990 through May 1991 at a public hospital in New York City. During this period, there were 3261 births at the hospital. Cocaine toxicology tests were ordered selectively in newborns with at least one of the following criteria: (1) no documented prenatal care, (2) known maternal history of illicit drug use, (3) maternal or newborn signs or symptoms consistent with drug exposure, or (4) birth outside the hospital. The study period im-

mediately preceded the implementation of a modified child welfare investigation and placement policy in New York State in June 1991. The new policy eliminated lack of prenatal care and extrahospital births as criteria for newborn toxicology.

Data Collection

Research staff gathered all information by systematic review of maternal and infant medical records using prepared coding forms. The chart reviewers were not aware of the specific goal of this investigation.

Statistical Analysis

Chi-square tests (for categorical variables) and *t* tests (for continuous, normally distributed variables) were used in conducting bivariate comparisons. Ordinal grouped variables were examined with the Kruskal-Wallis one-way analysis of variance. Multiple logistic regression was used to control simultaneously for several independent variables predicting discharge custody status. SAS software was used for all analyses.[8] Methods described by Schlesselman[9] were used to determine confidence intervals on multiple logistic odds ratios.

Results

During the study period, 99 infants were identified with positive urine assays for cocaine or benzoylecgonine. Reasons for toxicology testing (not mutually exclusive) were known history of drug use (64), clinical signs of drug use in mother or newborn (6), lack of prenatal care (31), and extramural delivery (11). Custody at newborn discharge (see Table 1) was to birth mothers (38%), other family members (25%), or agency foster care (36%). No differences were noted in reasons for testing between these custody groups.

Mothers who retained their infant's custody at discharge were younger at the index childbirth, although their first deliveries occurred at an older age (both *P*s < .05). Mothers who kept their newborns were also less often Black ($P < .01$). They were more likely to live in their own home and to have fewer previous children and any prenatal care (all *P*s < .05). Education level (high school completion) did not differ by discharge status or ethnicity. Reported history of substance use did not differ in the three custody groups.

Of mothers with previous children, those who retained custody at discharge were less likely to have had previous reporting to the local or state child welfare agency ($P < .0005$; Table 2). Index newborns with prior siblings in agency or family foster care were more likely to have been discharged to nonmaternal care. Among 50 mothers with prior child welfare records (range = 0 to 9 children, median = 2 children per mother), 109 prior children were known to have been placed out of maternal care in the past, and 107 children were placed out of maternal care at the time of the index birth. The number of prior children placed out of maternal care was higher among mothers whose index children were not discharged to their custody ($P = .095$, Kruskal-Wallis test). Newborn characteristics of the study subjects (Table 3) did not differ by discharge custody status.

TABLE 1—Characteristics of Mothers of 99 Cocaine-Positive Newborns, by Discharge Custody Status

	Discharge Status		
	Mother (n = 38)	Other Relative (n = 25)	Agency (n = 36)
Mean maternal age, y (SD)	26.8 (5.3)	27.2 (4.3)	29.8 (4.6)[a]*
Mean maternal age at first birth, y (SD)	20.4 (3.9)	20.1 (3.2)	18.3 (4.1)**
Ethnicity, no. (%)***			
Hispanic	23 (61)	8 (32)	9 (25)

TABLE 2—Child Welfare History of Mothers of 99 Cocaine-Positive Newborns, by Discharge Custody Status

	Discharge Status		
	Mother (n = 38)	Other Relative (n = 25)	Agency (n = 36)
Prior child welfare record,[a] no. (%)	5 (13)	13 (72)	27 (75)
No prior record, no. (%)	23 (61)	6 (24)	6 (17)
First child, no. (%)	10 (26)	1 (4)	3 (8)
Prior child placed in foster care,[a] no. (%)	2 (5)	13 (52)	21 (58)
Prior children in foster care,[a] median no. (range)	0 (0–2)	1.5 (0–7)	2 (0–9)

[a]Agency or family foster care.
*$P < .0005$ (chi-square test comparing groups with previous children).

Two models were used in performing a multiple logistic regression analysis (Table 4): (1) agency (nonfamily) placement vs mother or other relative and (2) nonmaternal placement (relative or agency) vs mother. Independent dichotomous (prior child welfare involvement, Black vs non-Black, no prenatal care, not living in own home, primiparous, and newborn gender) and continuous (maternal age at index and first birth and newborn weight) variables were entered simultaneously in both models.

Previous involvement of the mother with the child welfare agency was the strongest predictor of nonmaternal discharge placement; it was less strongly related to nonfamily placement. Black race

TABLE 3—Neonatal Characteristics of 99 Cocaine-Positive Newborns, by Discharge Custody Status

	Discharge Status

At first child	0.76	0.62, 0.93	0.95	0.79, 1.13
At index delivery	1.16	1.03, 1.31	0.97	0.85, 1.11
Newborn weight, g[c]	1.00	...	1.00	...

[a]Odds ratio of risk for agency placement vs mother or family, controlling for other variables.
[b]Odds ratio of risk for agency or family placement vs mother, controlling for other variables.
[c]Continuous independent variable (odds ratio of the change in risk with change of one unit of independent variable in same direction).

was also predictive of discharge away from the mother and less predictive of nonfamily discharge custody. In neither model were any interactions noted between ethnicity and prior child welfare reporting. In addition, lack of prenatal care predicted nonfamily placement, and the mother's lack of her own home was associated with her not gaining custody of her newborn at discharge. Lower age of the mother at first delivery and older age at delivery of the index newborn were also predictive of nonfamily placement.

Discussion

The discharge custody status of newborns known to be cocaine exposed may be influenced by many factors, including local policies and practices,[3] individual differences influencing parenting ability and the home environment, and the availability of a family support network. Some of these placements may have been emergency dispositions prior to final court action and may not necessarily reflect court-ordered custody decisions. Others may have been voluntary placements by mothers hoping for judicial leniency in final custody decisions.

Federal statutes require that, before the placement of a child in foster care, "reasonable efforts" be made to prevent the need for removal and to enable the child to return to his or her home.[10] In New York, state social service statutes call for families to be kept together whenever possible, not to be separated solely because of poverty, and to be offered services to "maintain and strengthen family life."[11] These statutes affirm "the state's first obligation" as assisting "the family with services to prevent its break-up or to reunite it" when the child is separated.[12,13] Unnecessary protracted foster care "may deprive these children of positive, nurturing family relationships and have deleterious effects on their development."[14] Courts may order agencies to "encourage and strengthen" the parental relationship, including helping parents with "housing, employment, counselling, medical care or psychiatric treatment."[15,16] Also, courts and parents may agree to a temporary separation from the child with plans to reunite after successful drug treatment.

The role of prior child welfare involvement in increasing the likelihood of removal of subsequent newborns from the home raises questions about compliance with federal and New York State regulations. These statutes explicitly require reasonable efforts for family unification, while early newborn placement may result in long-term separation of children from their birth families. Although repeated removal of newborns from the same addicted mother may reflect her lack of response to drug treatment or other services, it may also indicate the system's failure to individualize assessments and to adequately provide needed services. An overtaxed child welfare system with limited resources may focus on short-term goals of perceived child protection rather than the broader efforts needed to protect children by strengthening and preserving family units.

Reunification of foster children with their birth parents has been supported because (1) the child's well-being is enhanced by continuous caretaking, (2) the birth parents have legal and social priority as permanent caregivers, (3) the child may be psychologically harmed as a result of the separation of foster care, and (4) the state avoids the cost and recruitment of foster parents.[17] But in an era of shrinking resources for family support, limited drug treatment services for women with children,[18] and staff cutbacks, such reunification is more difficult to achieve. In addition, child welfare agencies are under legal pressure to make rapid determinations of newborn custody status.

> Families that could be helped are all too often simply written off, as yet another child begins a career of foster placement. In the name of protection, crimes are being committed not only against children but against parents, who are

left without authority or responsibility and whose only remaining power is to create more children.[19]

In this context, previous records of reporting to these authorities, rather than triggering assistance in family reconstruction, may become a convenient way to identify mothers "at risk" for subsequent parenting deficiency. Overworked and understaffed child welfare agencies may view prior reports as indicators to separate mother and infant until a court determination is made; however, this approach may not be most beneficial to family preservation. The knowledge of cocaine exposure may itself be influenced by social or racial bias in decision making for drug toxicology testing and reporting.[20] Such biases may also have an impact on custody disposition decisions. Furthermore, in a selectively screened population such as ours, newborns with positive cocaine toxicology may differ from the general population of cocaine-exposed newborns at this or other hospitals.

Reasons for ethnic disparity in patterns of newborn custody disposition other than direct bias may pertain. Multigenerational patterns of substance use may differ across ethnic groups. Blacks in the population under study may have had less available extended family support to allow mothers or other family members to retain newborn custody because of the severity of drug addiction, unemployment, homelessness, and premature morbidity and mortality. Access to health and legal services and voluntary foster placement may also vary with ethnicity. Of additional concern in these data are the independent effects of lack of housing and prenatal care on newborn discharge dispositions, since these are important indices of social deprivation. Thus, lack of social resources for housing and accessible health care may predispose to loss of child custody.

The cocaine epidemic of the late 1980s led to an overwhelmed child welfare and foster care system and to a plethora of "boarder babies": newborns housed for weeks and months in hospitals for lack of court-determined discharge placement. As this crisis leveled off, New York state and city social service authorities implemented modified policies concerning neonatal urine toxicology screening (memoranda of June 1991 from the New York State Department of Social Services, the New York City Health and Hospitals Corporation, and the New York City Human Resources Administration–Child Welfare Administration). These changes eliminated lack of prenatal care and extrahospital births as sufficient criteria for newborn toxicology testing. Parental drug use is no longer sufficient to determine child maltreatment, although evidence of such use still triggers a child protective investigation. Time limits were set for family and home investigations after reports to authorities of newborns with positive drug toxicologies. The results of these policy changes are not yet clear.

The medical chart data in this study did not afford complete information to understand fully the determinants of discharge custody decisions. Information was usually lacking on past maternal drug use and treatment, detailed family or home assessments, whether foster placement was voluntary, and specific location of prior foster placements, although child welfare investigators presumably had access to these data. Further research is needed to understand the process of discharge custody decision making in regard to drug-exposed newborns. Prospective evaluation of long-term outcomes of these decisions for children and families needs special attention. In particular, the effects of early separation on mother–infant attachment and maternal self-esteem need elucidation. Most important, studies are needed of interventions to enhance the cohesion and reconstruction of families with substance abuse problems. The societal costs of foster care, family disruption, and untreated chemical dependency are considerable. Removal of the drug-exposed infant from his or her family may not be uniformly beneficial to the child, the family, or society. □

Home Health Clients: Characteristics, Outcomes of Care, and Nursing Interventions

ABSTRACT

Objectives. The purpose of the study was to provide descriptive data about the characteristics of home health clients, the services that nurses provide, and the outcomes of those services. Such data have been sparse.

Methods. This study examined 2403 home health clients served by four agencies in Nebraska, New Jersey, and Wisconsin. Demographic, health history, and clinical data were analyzed. The Omaha System was used as the model for describing and measuring data specific to clients' health-related problems, nursing interventions, and outcomes of care.

Results. The median age of home health clients was 68.6 years. Nurses conducted 70% of all home visits, identified 9107 client problems, and provided over 96 000 interventions. Between admission and dismissal, clients improved by at least 0.52 point on three 5-point problem-specific outcome subscales (Knowledge, Behavior, and Status).

Conclusions. These data show important characteristics of home health clients in a large national sample. They also support the usefulness of the Omaha System in describing and quantifying nursing practice in the community health setting. The magnitude of positive client change between admission and dismissal suggests that community health services do make a difference. (*Am J Public Health.* 1993;83:1730–1734)

Introduction

What are the characteristics of home health clients and the services they receive in today's complex milieu? What effect do nursing services have on those clients? In this article we report the findings of a recent Visiting Nurse Association of Omaha research project that used three classification schemata for examining client–nurse interactions. The schemata are referred to as the Omaha System.

A variety of client characteristics and trends are evident in the health care literature. One of the most extensive documents about current and anticipated health-related problems of the US population is *Healthy People 2000.*[1] That publication, however, emphasizes medical diagnoses; it addresses home health issues, the effect of nurses, and nursing-focused client concerns in a relatively limited manner. Research conducted in community health settings contributes to the understanding of home health clients. Three nationally reported home-care client studies documented the increasing severity of illness and decreasing reimbursement sources. However, the studies emphasized medical diagnoses rather than nursing services.[2–4]

Nurses, the primary providers of home health services, have designed few studies involving home health clients and nursing practice. Rarely have they systematically explored or quantified physical, environmental, and social characteristics of home health clients and the services they receive.[5–7] Few nurse researchers have investigated the effects of health care services on clients, especially on home health clients.[8–11] Increasingly, however, all health care providers are receiving pressure from reimbursement sources, accreditors, and legislators to consider the outcome effectiveness of client services.[12–15] Establishing the relationship between nursing services and client progress is an important element of a minimum data set useful to the nursing profession.[16] The purpose of a nursing minimum data set is to provide an abstraction tool for standardized, comparable, and essential data. Williams[17] noted the importance of a nursing minimum data set but cautioned that pilot tests were needed, especially tests involving public health and home health settings.

Noteworthy for nurses is a compilation of studies edited by Waltz and Strickland.[18–21] It includes three studies that involve client outcome measurement instruments for community health nurses. Nursing diagnoses were used as the framework for home health measurement tools in two of the studies. Nursing diagnoses were based on the Omaha Problem Classification Scheme[22] and on North American Nursing Diagnosis Association vocabulary.[23]

Methods

The Omaha System research project, carried out from 1989 through 1983, was designed to accomplish multiple purposes. In this article we report the frequency and type of the clients' problems; the clients' problem-specific knowledge, behavior, and status outcome changes; and the frequency and type of nursing in-

At the time of the study, Karen S. Martin and Nancy J. Scheet were with the Visiting Nurse Association of Omaha, Omaha, Neb. Mary Ruth Stegman is with Creighton University, Omaha.

terventions occurring in diverse home health agencies. Elsewhere we describe research findings in addition to the client demographics and service characteristics noted in this article; the conceptual framework and structure of the Omaha System; previous research; and the system's applicability, reliability, validity, and efficiency.[24-26]

The Omaha System has been described as a comprehensive schema of nursing diagnoses, client outcomes, and nursing interventions.[25,27,28] The three schemata were developed during a series of research studies conducted between 1975 and 1986. The Omaha System provides a framework for merging a practice and documentation system and offers a method of organizing client and provider data and integrating them into a manual or automated management information system.

Omaha System Schemata

The first component of the system is referred to as the Problem Classification Scheme; it is a client-focused taxonomy of nursing diagnoses. The most global level of the scheme consists of domains called Environmental, Psychosocial, Physiological, and Health Related Behaviors. At more specific levels, these domains comprise 40 client problems, each with a cluster of signs and symptoms. One of the problems from the Physiological domain is circulation; it was the most frequently occurring problem in this study.

The second component of the Omaha System, the Problem Rating Scale for Outcomes, consists of three 5-point Likert-type subscales. The Knowledge, Behavior, and Status subscales offer a numeric measurement framework with which to evaluate changes in the clients' knowledge, behavior, and status in relation to specified health-related problems and selected time frames. At admission to service, a client who exhibits a circulation impairment problem may have a status rating of 2 as evidenced by pitting edema of the ankles and lower extremities. Ideally, with nursing care, client involvement, and a medical plan of care, at dismissal the client may have no edema at dismissal and therefore a status rating of 5.

The third component of the Omaha System is an Intervention Scheme. This is a hierarchical organization of nursing actions that is designed to describe and quantify problem-specific plans and interventions. At the most global level, the Intervention Scheme comprises four broad categories of interventions: Health Teaching, Guidance, and Counseling; Treatments and Procedures; Case Management; and Surveillance. More specific targets or objects of nursing actions and client-specific information are used in conjunction with the categories. For the client who has a circulation impairment problem, the nurse is likely to (1) make a home visit, complete a physical assessment, and provide care and (2) document the intervention category referred to as Health Teaching, Guidance, and Counseling; the target of cardiac care; and specific details about fluid restrictions and potentially contributing factors such as smoking and stress.

Sample

Four home care agencies were purposively selected for diversity in relation to their history of using the Omaha System, size, organization, length of operation, and geographic location. Client records were included in the sample if the clients were admitted and dismissed during each agency's 18-month data collection period, had at least one physiological problem, and received at least two home visits from a nurse.

Home health nurses who visited clients and documented services in client records participated in the study if they had been employed at the agency for at least 3 months, used the Omaha System to document client services, and participated in the initial 4-hour orientation session. All nurses who attended were introduced to the Omaha System schemata and observed a videotape simulating a nurse–client home visit. Working independently, they identified and recorded the client's problems, outcome scale ratings, and interventions.

Data Collection

A two-part client data collection form was developed, pilot tested, and revised. The first part addressed demographic and health history information, including payment source. Service data included the first and last visit dates and number of home visits made by various types of caregivers. The second part included specific service data based on the three schemata of the Omaha System. Data collection focused on client problems, problem-specific knowledge, behavior, and status outcome changes, and interventions provided by various community health staff members.

Procedures

Project personnel who met specific criteria were selected to serve as data abstractors. Criteria included Omaha System expertise, community health experience, and demonstrated proficiency in documentation. Preliminary reliability of project personnel was established prior to data collection and visits to the four sites were scheduled every 3 to 4 months. The data collectors monitored record data to ensure that all staff at the sites were implementing the Omaha System appropriately. They selected client records on the basis of established criteria and abstracted data from these records. Random samples of abstracted data were assessed for reliability throughout the data collection period.

Analysis

Descriptive and inferential data analyses were performed with the Statistical Analysis System (SAS).[29] To maintain confidentiality, each client record was assigned a number and all data were analyzed in the aggregate by agency or total sample. Frequencies and *t* tests were used for the descriptive analysis presented in this article.

Results

Data were collected between October 1989 and October 1991. A total of 2403 clients and their records were admitted into the sample. The client records were obtained from a large urban Nebraska agency (n = 1063), a large urban New Jersey agency (n = 896), a small rural Nebraska agency (n = 263), and a small rural Wisconsin agency (n = 181).

Demographic and Health History

The home health clients served by the four agencies presented a distinctive composite demographic profile. Older, female, married or widowed Caucasian clients dominated the sample. The clients' ages ranged from birth to 104 years; the median age was 68.6 years. Females accounted for 58% (n = 1389) of the sample. Approximately 39% (n = 925) of the sample were married and 35% (n = 850) were widowed. Eighty-five percent (n = 2045) of the clients were Caucasian, 12% (n = 293) were African-American, 2% (n = 43) were Hispanic, and 0.3% (n = 8) were Asian, and another 0.3% (n = 7) were Native American.

The clients' living accommodations, caregiving arrangements, dependency characteristics, and dismissal status were noted. Approximately 40% of the clients lived alone (n = 883), were independent in relation to functional status (n = 973),

TABLE 1—Frequencies of the Most Common Primary Medical Diagnoses of Home Health Clients, According to ICD-9-CM Diagnostic Groups

Diagnostic Group	Frequency (n = 2403)	%
Circulatory system disorders	572	23.8
Neoplasms	406	16.9
Injuries/poisonings	260	10.8
Respiratory system disorders	227	9.5
Endocrine, metabolic, and nutritional disorders	197	8.2
Digestive system disorders	151	6.3
Musculoskeletal system and connective tissue disorders	137	5.7
Ill-defined signs/symptoms	106	4.4
Skin and subcutaneous tissue disorders	82	3.4
Genitourinary system disorders	58	2.4
Other	207	8.6

Note. ICD-9-CM = *International Classification of Diseases*, 9th Revision: Clinical Modification.[30]

TABLE 2—Visits to Home Health Clients, by Caregiving Category

	No. Clients	Visits per Client			Total Visits
		Minimum	Maximum	Mean	
Nursing	2403	2	116	9.11	21 880
Home health aide	634	1	186	9.66	6122
Physical therapy	289	1	61	6.90	1993
Medical social work	249	1	12	1.86	462
Occupational therapy	32	1	29	6.84	219
Speech pathology	19	1	67	12.47	237
Total	2403	2	282	12.87	30 913

Note. Sample selection criteria required a minimum of two nursing visits. Clients could receive visits from one or more types of caregivers.

TABLE 3—Frequency of Problems Experienced by Home Health Clients (n = 2403), by Domain and Agency

Agency	Physiological		Health Related Behaviors		Psychosocial		Environmental		
	Frequency	%	Frequency	%	Frequency	%	Frequency	%	Total
Urban Nebraska	2183	68.3	782	24.5	208	6.5	21	0.7	3194
Urban New Jersey	3014	74.1	909	22.3	88	2.2	56	1.4	4067
Rural Nebraska	567	72.1	139	17.7	70	8.9	10	1.3	786
Rural Wisconsin	722	68.1	271	25.5	60	5.7	7	0.7	1060
All	6486	71.2	2101	23.1	426	4.7	94	1.0	9107

and were dismissed to self-care (n = 930). However, it should be noted that over 50% of the clients were partially dependent (n = 1207) and the remaining 10% were dependent (n = 223). Client dependency was also evidenced by the fact that 59% (n = 1425) of the clients required a spouse or adult child to serve as the primary caregiver and 30% (n = 731) of the clients were dismissed to family or friends.

Reimbursement of services is a critical issue for all home health agencies. Funding sources directly influence the length and amount of service provided to clients. In this study, Medicare was the primary source of reimbursement for 73% (n = 1755) of the clients. The length of service ranged from 1 to 375 days; the mean was 34.74 days.

The primary medical diagnoses of clients were categorized according to ICD-9-CM diagnostic groups.[30] The diagnostic groups that occurred more than 50 times are shown in Table 1; they account for 91.3% of the sample's diagnostic groups. The frequent occurrence of circulatory system disorders and neoplasms, accounting for 40% of the diagnoses, is consistent with national mortality trends. Within the ICD-9-CM diagnostic groups, the three specific medical diagnoses that occurred most frequently were diabetes mellitus, congestive heart failure, and cerebrovascular disease.

Clients' drug profiles were directly related to medical diagnoses. No drugs were prescribed for 67 clients. The 2336 clients who received at least one drug averaged 5.2 drugs per length of service for a total of 12 460 drugs. Cardiac drugs, analgesics and antipyretics, gastrointestinal drugs, diuretics, and central nervous system agents were the most frequently prescribed drugs.

The number of visits made to clients by each of six types of caregivers varied markedly during the clients' length of service (see Table 2). The length of service (range = 1–375 days; mean = 34.74 days) was mentioned above in relation to reimbursement. Nurses conducted 70% of all home visits. Because nurses were the focus of this study, it should be noted that sample selection criteria required a minimum of two nursing visits. Therefore, clients from each agency who received only one nursing visit or only visits from other types of caregivers were not included in the study; a relatively small number of clients were excluded from the research for these reasons. It should also be noted that the sampling plan used in this research reflects the purpose of the study and the number of nurses in the community health practice setting; the plan was not intended to diminish the importance of interdisciplinary contributions to client care.

Omaha System

Based on the sample of 2403 clients and the Problem Classification Scheme, home health nurses identified a total of 9107 client problems or nursing diagnoses. The mean number of problems per client was 3.79; the median was 3 and the mode was 2. Identified problems ranged from 1 to 15 per client. The frequency of problems from the Physiological, Health Related Behaviors, Psychosocial, and Environmental domains for the entire sample and for each agency is depicted in Table 3. For the total sample, problems in the Physiological domain accounted for 71% of all problems. Problems in the Health Related Behaviors domain accounted for 23% of the problems, whereas Psychosocial and Environmental problems accounted for approximately 5% and 1%, respectively. Although inclusion in the sample required that each client have at least one problem in the Physiological domain, the preponderance of physiological problems is typical of home health clients and their reasons for referral. The frequency of occurrence for the total sample and that for each agency were highly similar.

The second component of the Omaha System is the Problem Rating Scale for Outcomes. Table 4 shows the clients'

Knowledge, Behavior, and Status ratings at admission and dismissal for the entire sample and for each agency. It also depicts the average amount of change that occurred during the period of home health nursing service. Clients' Knowledge, Behavior, and Status ratings increased by at least 0.52 point overall. In addition, Table 4 shows the paired *t*-test scores and probability values for the test. The increase in each rating was greater than zero. The magnitude of the *t*-test values demonstrates the overwhelming consistency of clients' improvement in problem-specific knowledge, behavior, and status as they received service from home health nurses and other professionals. It should be noted that every client did not improve, especially on all three subscales. For example, some clients were admitted to an agency's hospice program and were expected to die relatively soon. Their status ratings associated with the primary medical diagnoses were expected to deteriorate.

The third component of the Omaha System is the Intervention Scheme used by nurses to document their actions as they provide nursing service to clients. The order of frequency of occurrence for the four intervention categories is the same for all four agencies: (1) Surveillance; (2) Health Teaching, Guidance, and Counseling; (3) Treatments and Procedures; and (4) Case Management. Table 5 depicts the frequency of interventions for the nine problems that occurred most frequently in the sample: circulation, integument, neuromusculoskeletal function, respiration, medication regimen, nutrition, bowel function, technical procedures, and pain. The order of frequency of occurrence for the four intervention categories was examined. Surveillance was the most frequently occurring intervention category for seven of the nine problems. Health Teaching, Guidance, and Counseling was the primary intervention category for medication regimen problems, and Treatments and Procedures was the most frequent intervention category for technical procedures problems.

TABLE 4—Outcome Ratings on Admission and Dismissal and Mean Increase, by Agency

	Agency				
	Urban Nebraska	Urban New Jersey	Rural Nebraska	Rural Wisconsin	Total
Knowledge rating					
Admission mean (SD)	2.60 (0.65)	2.52 (0.68)	2.65 (0.76)	2.87 (0.54)	2.60 (0.67)
Dismissal mean (SD)	3.18 (0.75)	3.19 (0.82)	3.40 (0.69)	3.54 (0.69)	3.25 (0.79)
Mean increase (SD)	0.58 (0.01)	0.67 (0.01)	0.75 (0.03)	0.67 (0.02)	0.65 (0.006)
t test[a]	45.24	51.71	27.08	32.96	79.91
Behavior rating					
Admission mean (SD)	2.60 (0.66)	2.86 (0.71)	2.75 (0.86)	3.09 (0.65)	2.80 (0.72)
Dismissal mean (SD)	3.16 (0.81)	3.35 (0.84)	3.48 (0.88)	3.60 (0.79)	3.32 (0.84)
Mean increase (SD)	0.56 (0.01)	0.47 (0.13)	0.73 (0.03)	0.51 (0.02)	0.52 (0.006)

Note. In the sample of 2403 clients, 9107 problems were identified.

Discussion

This study is unique because it was designed from a nursing perspective and included analysis of an extensive national home health client sample. The analysis demonstrates the complexity of the clients being served by four community health nursing agencies in Nebraska, Wisconsin, and New Jersey. Indeed, the age, caregiving requirements, dependency, and dismissal status of the clients from each agency were very similar. The large number of clients whose services were reimbursed by Medicare further suggests that most clients are homebound, since Medicare regulations require that recipients of service be homebound. The extent of chronic illness experienced by clients in the sample is supported by the most frequently occurring medical diagnoses and the number and type of client problems in the Physiological domain. Client characteristics noted in this study and the dramatic national aging trend confirm the presence of a significant population of frail elderly persons in our society.

The results of this observational study support the usefulness of the Omaha System in describing and quantifying nursing practice. The system provides a reliable and valid method for gathering large quantities of pertinent client problem, nursing intervention, and client outcome data from differing home health agencies.[24–26] Armed with data from individual clients as well as aggregate data, nurses and administrators can use the Omaha System to guide practice, struc-

ture documentation, and organize a client management information system. Such a method reflects the criteria required for a nursing minimum data set.[25]

The ability of the Omaha System to characterize large aggregate populations across different agencies has great potential for future research. Administrators, practitioners, and policymakers can use aggregate data as a basis for examining the client case mix and relating that mix to specific nursing diagnoses, interventions, and client outcomes. Furthermore, the cost-effectiveness of such relationships can be evaluated, an action that is of increasing interest to policy makers. Changes in clients' knowledge, behavior, and status outcome ratings between admission and dismissal in such a large sample strongly suggests that home health service does make a difference. In fact, this is the largest documented observational study that has examined clients' knowledge, behavior, and status both before and after nursing intervention.

Home health nurses can and do provide multidimensional and comprehensive services that they can describe and quantify. They identify and document client problems specific to the referral reason as well as other problems that they consider priorities. Even when Treatments and Procedures was the prescribed intervention, nurses frequently documented Surveillance; Health Teaching, Guidance, and Counseling; and Case Management interventions as well. Such professional practice suggests that nurses recognized the interrelated, complex nature of client problems, the responsibility to judge whether prescribed services were compatible with the home environment, and the need to provide diverse interventions before problem resolution occurred. Nurses should continue to conduct research that addresses client characteristics and the impact of nursing services. Such research is especially timely because of the increasing demand to measure the outcome effectiveness of health-related services. □

Cause of Death in Patients with End-Stage Renal Disease: Death Certificates vs Registry Reports

Thomas V. Perneger, MD, MPH, Michael J. Klag, MD, MPH, and Paul K. Whelton, MD, MSc

ABSTRACT

Objectives. The purpose of this study was to assess agreement on cause of death reporting in end-stage renal disease patients by comparing death certificates and reports to an end-stage renal disease registry.

Methods. Death certificates and registry reporting forms were retrieved for a random sample of 335 treated end-stage renal disease patients who died between 1980 and 1986 in Maryland. On the registry form, patient death was ascribed to 1 of 22 precoded causes by the patient's nephrologist of record. Corresponding death certificates were coded, according to rules of the *International Classification of Diseases*, 9th edition, by a trained observer unaware of the registry report. Agreement was measured by the kappa statistic.

Results. Overall cause of death agreement was poor (31%), and varied by the following categories: renal disease (40% on death certificates vs 0% on registry reports), cardiovascular disease (26% vs 47%), infectious disease (16% vs 22%), cancer (7% vs 5%), and withdrawal from therapy (0% vs 3%). Agreement was higher for transplant recipients than for dialyzed patients.

Conclusions. Death certificates and registry reports yield different descriptions of mortality in end-stage renal disease patients. These sources of information should not be used interchangeably. Improvements to *International Classification of Diseases* coding of renal diseases and the determination of the reliability and validity of the US Renal Data System reporting process are necessary steps in the development of renal disease epidemiology. (*Am J Public Health.* 1993;83:1735–1738)

Introduction

Limitations of mortality statistics were first discussed by Graunt in his *Bills of Mortality*.[1] The cause of death selected depends on the source of information[2]: clinical records, autopsy findings, and death certificates consistently disagree on cause of death.[3–5] The selection is also affected by the disease classification system in use.[2] Standard rules proposed by the *International Classification of Diseases*, 9th edition[6] (ICD-9), are deemed "suboptimal for many biomedical applications,"[7] which explains why disease registries often use customized cause-of-death reporting procedures.

One such registry, the US Renal Data System,[8] collects information, including cause-of-death reports, on patients treated for end-stage renal disease in the Medicare End-Stage Renal Disease Program. Regional registries[9,10] and the national US Renal Data System[11] identify cardiovascular and infectious diseases as the most common causes of death in end-stage renal disease patients. To assess the reliability of this information, we examined the level of agreement between causes of death reported to the Maryland regional registry (now part of the US Renal Data System) and corresponding information derived from death certificates.

Methods

The study sample (n = 378) was drawn at random from 757 patients enrolled in the Maryland Medicare End-Stage Renal Disease Program who died between January 1, 1980, and December 31, 1986.

Matching of Maryland registry information with death certificates, based on name, age, and date of death, was successful for 335 (89%) patients. For 37 patients, linkage was accepted despite a minor mismatch: 1-day difference in date of death (n = 8), middle name used as first name (n = 3), misspelled first name (n = 10), or one-letter substitution in last name (n = 16). The remaining 43 patients (11%) died outside Maryland, or their records contained errors causing a mismatch.

Cause of death was reported to the registry by the patient's attending nephrologist according to 1 of 22 categories specified on the end-stage renal disease death notification form (numbered categories in Table 2). Photocopies of original death certificates were obtained from the Maryland Vital Statistics Office. An investigator (T.V.P.) trained in ICD-9 coding[6,12] selected the underlying cause of death on all death certificates without knowledge of the cause reported to the registry. Coding was repeated 3 months later. Twenty-three inconsistencies between the first and second codings were resolved by formal reference to coding rules. Causes of death derived from death certificates were grouped according to the 22 registry cause-of-death

categories. Categories for renal diseases and for diabetes were added because no equivalent was found on the registry list (unnumbered categories in Table 2).

Frequency distributions, cross tabulations, agreement between sources, and corresponding kappa statistics were obtained. The kappa statistic represents agreement achieved beyond that expected by chance alone.[13,14] A 20 × 20 cross tabulation (registry codes 5 and 8, corresponding to air embolism and vascular access hemorrhage, were not used) was used to compute overall agreement and the kappa statistic in the total sample and for demographic strata. A 2 × 2 table (specified cause vs other) was used to compute disease-specific agreement and kappa in the total sample only. National Institutes of Health General Clinical Research Centers computerized data management and SAS software were used in conducting analyses.

Results

The study sample was approximately equally divided by gender and race (Table 1). Of the non-Whites, 140 were Black and 1 was Hispanic. The average age at death was 54 years.

Distributions of cause of death showed a striking difference ($\chi^2(19) = 209$, $P < .001$) between the two sources of information (Table 2). In registry reports, the most frequent cause of death was cardiovascular disease (47%), followed by infectious diseases (22%). Renal failure was not reported as an underlying cause of death, except as reflected by the 27 (8%) deaths attributed to pericarditis, hyperkalemia, and withdrawal from therapy. No deaths were attributed to diabetes mellitus. In 1 in 10 patients, the cause of death was reported as unknown or the information was missing.

The most frequent cause of death reported on death certificates was renal disease. Forty percent of deaths were ascribed to specific kidney diseases, chronic renal failure, or end-stage renal disease. Cardiovascular diseases accounted for one in four deaths, and diabetes mellitus accounted for 13% of deaths. No deaths were ascribed to withdrawal from therapy, although it was mentioned as a contributing cause on three death certificates.

The overall agreement was 31%, and the corresponding kappa was .24 (Table 3). Agreement varied little by gender, race, or age; better agreement was achieved among transplanted than among nontransplanted patients. Agreement did not vary meaningfully with increasing interval between initiation of end-stage renal disease therapy and death. Disease-specific agreement was good for cancer, moderate for infectious disease, and poor for cardiovascular disease.

Discussion

This study revealed substantial differences between cause-of-death reports made to two information systems for the

same end-stage renal disease patients. Cardiovascular diseases and complications of therapy were prominent in registry reports, while renal diseases were most frequent on standard death certificates. The two sources agreed in fewer than a third of the patients, and the kappa statistic confirmed poor agreement.[14]

The discrepancy could stem from insufficient reliability or validity of either or both reporting systems. Reliability may have been affected by the lack of training of the certifiers and by interrater variability, given that different persons usually provided information to each source. Validity of cause-of-death assessment in patients with renal failure may be particularly problematic. Uremia was recognized as a poorly documented cause of death in 1912.[15] Since then, trends in kidney disease mortality have often been discussed in terms of changes in certification patterns.[16–20] Before widespread availability of end-stage renal disease therapy, death certificates identified renal disease in only 67% of patients dying of uremia.[21] Even when mentioned on a death certificate, a renal disease is coded as the underlying cause of death only about 20% of the time.[22]

Additional problems are inherent to the ICD-9. Today, most patients with end-stage renal disease do not have a "primary" renal disease but suffer from complications of diabetes or hypertension. Nephropathy complicating a systemic disease is usually indicated by the third or fourth digit in the ICD-9 code, which is routinely omitted in summary statistics and may be misstated (for diabetic nephropathy, the ICD-9 code is 250.3, but the code is 250.4 in the ICD-9 Clinical Modification). Moreover, selection of the *underlying* cause of death is inconsistent: for "myocardial infarction due to diabetes with nephropathy," diabetes mellitus is the underlying cause of death, while for "myocardial infarction due to hypertensive renal disease," coronary disease overrules hypertensive disease by a specific coding rule.

Another plausible explanation is that death certificates and registry reports do not measure the same concept of "cause of death." The registry reporting system emphasizes possible indicators of quality of care in the Medicare End-Stage Renal Disease Program, such as withdrawal from therapy, vascular access hemorrhage, or hyperkalemia, which may be poorly reported on standard death certificates. These are mechanisms of death rather than underlying causes. Incidentally, even agreement on mechanism of death can be difficult to achieve: recognition of "social and contextual factors" is incompatible with the registry's emphasis on biological mechanisms.[23]

The registry reporting of cause of death may address legitimate needs of the Medicare End-Stage Renal Disease Program, but it has limited external validity. Notably, the registry list includes neither renal nor systemic diseases as possible causes of death in end-stage renal disease patients. Thus, US Renal Data System mortality statistics cannot be compared with ICD-based mortality reports, and studies using registry data[10] may have little in common with studies using medical records[24] or a combination of sources.[25] Selection of a cause of death in end-stage renal disease patients deserves more attention from renal disease nosologists and US Renal Data System information managers. Adjustments to the Renal Data System database may include coding of multiple cause-of-death data[26] and separate reporting of cause-of-death and quality control information. Clarification of ICD-9 coding for kidney diseases is also warranted. Increased compatibility between the two information systems may greatly increase their usefulness. □

Infectious Diseases and Mortality among US Nursing Home Residents

Consuelo Beck-Sague, MD, Shailen Banerjee, PhD, and William R. Jarvis, MD

ABSTRACT

Data collected in the 1985 National Nursing Home Survey were analyzed to identify risk factors for infections and mortality and to explore their relationship in US nursing homes. An infection was recorded in 166 609 (14%) discharges. Risk of pneumonia was found to be higher among bedbound patients (54.5 vs 13.1 per 100 discharges); urinary tract and other infections were most frequent among residents with indwelling catheters (6.6 vs 1.0 per 100 discharges). Residents with pneumonia were more likely than those with other infections to die (35% vs 28%), or be discharged to hospitals if alive (94% vs 66%). Thus, immobility and catheterization were associated with infections in US nursing homes, and pneumonia was found to contribute to mortality. (*Am J Public Health.* 1993;83:1739–1742)

Introduction

Of the 2.1 million persons over age 85 in the United States, 22% reside in nursing homes.[1] The population of persons aged 85 years and older will exceed 4 million by the year 2000.[2] Risk of infection in nursing homes ranges from 3.3% to more than 15%.[3–5]

Infections and their relationship to mortality in nursing homes have been studied.[5–9] This is the first study that uses a population-based national survey to identify risk factors for infections and mortality and to explore their relationship in US nursing homes.

Methods

Collection of Data

Data for this study were taken from the 1985 National Nursing Home Survey conducted by the National Center for Health Statistics (NCHS). The survey included all types of nursing and related-care homes with at least three beds.[10] Sample data were collected from 20 479 US nursing homes by applying a stratified two-stage probability design; methods have been described previously.[10] Data collected included measures of the functions of residents, and admission and discharge diagnoses, coded using the *International Classification of Diseases,* 9th revision, Clinical Modification.[11]

Case Definition

Discharges were defined as cases of infection if the survey interviewer recorded an infection at discharge. These diagnoses were grouped in coding as pneumonia, urinary tract infection, and infectious and parasitic diseases.

Statistical Methods

Rates of infectious diseases were calculated for discharged residents by selected resident characteristics. Because some residents had infections diagnosed on admission, residents with the same infection at admission and discharge were excluded from the analysis so that the risk associated with nursing home residence could be assessed. Weights provided by the NCHS were used to obtain estimates for national averages.[10] Standard errors for relative risks were obtained by using constants obtained from the NCHS.[10,12,13] Rate ratios and their 95% confidence intervals were calculated as estimates of relative risk.[12] Significance of relative risks was tested by calculating standard normal variates and the corresponding probabilities. Duration of stay was estimated for groups of discharged residents and compared by calculating chi-squares and corresponding probabilities from the contingency tables generated.[14] Infections among discharge diagnoses were compared by month of discharge to identify seasonal variation in the incidence of infections and mortality. Rates of discharge to health care facilities versus residential settings and rates of fatality were also calculated and compared.

Results

Study Population

We reviewed information on 1 220 816 residents (projected from a sample of 6017

residents) discharged from 19 068 US nursing homes (projected from 1078 homes). These residents ranged in age at discharge from 2 to 109 years (median = 82 years) and in duration of residence from less than 1 month to 53 years (median = 4.5 months). Additionally, 62.8% were female.

Infectious Diseases in Discharged Residents

Infections were included in the diagnoses at discharge of 166 610 (14%) residents. In 82 192 (49%), pneumonia was among the discharge diagnoses; in 56 666 (34%), urinary tract infections were included; and in 27 752 (17%), bacterial, viral, and parasitic infections were cited. Among 84 695 (51%) residents with primary diagnoses of infections at discharge, pneumonia (64%), urinary tract infection (19%), or another infection (17%) was the primary discharge diagnosis.

In 33 050 discharged residents with urinary tract infections and bacterial, viral, and parasitic infections, these infections were not included in the admission diagnoses, which suggests that they were acquired in the nursing home. Rates of infection were significantly higher among residents who were bedbound (4.1 vs 2.1) or incontinent for stool (4.5 vs 1.4) or urine (3.9 vs 1.0) (Table 1). The highest risk was associated with indwelling catheterization (6.6 vs 1.0).

In 60 334 residents with a discharge diagnosis of pneumonia, pneumonia was not included in the admission diagnoses, which suggests again that, in these residents, the infection was acquired in the nursing home. Rates of pneumonia at discharge were highest among residents who were bedbound (8.2 vs 3.3) or incontinent for stool (7.9 vs 2.6) or urine (7.8 vs 2.6) (Table 2). Indwelling catheterization was not as strongly predictive for pneumonia as it was for other infections, and the risk was not statistically significant. Prior stay in the nursing home was longer for residents with pneumonia (median = 6.4 months) than for other residents (median = 4.3 months, $P < .001$).

Seasonal variation was apparent among residents who had pneumonia at discharge (Figure 1). Almost 50% were discharged from January through April. Peak pneumonia and mortality associated with pneumonia coincided with the peak incidence of influenza cases in the United States during 1985 and 1986.[15] No seasonal variation was seen among discharges with infections other than pneumonia (Figure 1).

Fatality and Discharge Outcomes

Fatality rates were highest among residents who were bedbound (54.5 vs 13.1), incontinent (46.7 vs 11.0), or catheterized prior to discharge (4.3 vs 9.7), or who had pneumonia (35.3 vs 28.1) (Table 3). Among residents discharged alive, those whose di-

agnoses included pneumonia were more likely to be discharged to a health care facility than other residents (54 507/58 248 [94%] vs 535 937/817 656 [66%], $P < .001$), who were more likely to transfer to residential settings. Residents whose diagnoses included urinary tract infections and other infections excluding pneumonia were also more likely to be transferred to health care facilities (50 697/60 447 [84%] vs 485 240/757 209 [64%], $P < .001$).

Discussion

Pneumonia appears to be associated with considerable morbidity and mortality in US nursing homes. The striking seasonal variation of pneumonia as a discharge diagnosis in nursing homes suggests an association with influenza activity. It has been recognized that more than 80% of influenza-related deaths occur in the elderly.[16,17] Increases in immunization levels in nursing homes from 36% in the 1979/80 season to 71% in the 1985/86 season were reported, but the influenza epidemic of 1985/86 was characterized by considerable pneumonia mortality among elderly institutionalized persons.[16–19] A low immunization level is associated with the occurrence of influenza outbreaks in US nursing homes.[19]

Factors related to infections and death in nursing home patients include nonambulatory status. Aspiration and other outcomes associated with immobility have been previously identified as risk factors for urinary tract infection, pneumonia, and death.[4,9,20–23] Rehabilitation of elderly nursing home residents is controversial because the need for restoring mobility may be poorly understood, but mobility may reduce incontinence, infections, and mortality.[24–26] Delay in evaluating the signs of infection and instituting treatment may also contribute to the high fatality rate of residents with pneumonia.[20,27]

Assessment of infection control procedures in nursing homes has identified infrequent use of proven methods to reduce risk of urinary tract infections.[28] The sealing of catheters and use of prophylactic antimicrobials should be explored.[29]

Some aspects of the survey and study design limit the applicability of these findings. No information was available to assess the preventability of risk factors or to evaluate infection control or immunization programs. Exclusion of residents with the same infection at admission and discharge may have also excluded some residents for whom the discharge infection was a completely new event. Those with infections that were acquired in the nursing home and resolved before discharge were excluded. Finally, population estimates for some factors are based on small (fewer than 1000 discharges) samples. Nevertheless, this study suggests that

Nemesis Revisited: Tuberculosis Infection in a New York City Men's Shelter

ABSTRACT

In November 1990, a screening was conducted to determine the point prevalence of tuberculosis infection in a volunteer sample of homeless men (n = 161) living in a congregate shelter in New York City. Of those for whom we have results (n = 134), 79% were positive for tuberculosis. The mean length of shelter stay from date of shelter entry was 31.8 months and was significantly associated with the tuberculosis infection rate. The findings suggest that crowded living conditions and the presence of a stable resident pool in crowded congregate shelters may be associated with transmission of tuberculosis infection. Introduction

Nationally, the number of new cases of tuberculosis increased by 5% in 1989 and by 10% in 1990. The increase has been largely among 25- to 44-year-old men. This demographic finding coincides with—although it is not necessarily causally related to—the epidemic of acquired immunodeficiency syndrome (AIDS) and the increase in homelessness. In New York City alone, 3520 new tuberculosis cases were reported in 1990, representing a 38% increase over the number of new cases in 1989. This incidence level in New York City constitutes approximately 15% of all US cases reported in 1990.[1]

The prevalence of asymptomatic tuberculosis infection among the homeless has been reported to be as high as 22% to 50%.[2,3] In an immunocompetent population, it is estimated that only 25% of those exposed to tuberculosis become infected and that 10% of this subgroup go on to develop clinical disease.[4] However, the homeless are at greater risk for immune suppression because of poor nutrition, inadequate rest, and intercurrent medical illness. Among homeless men, 15% to 25% have also been found to have a lifetime history of a psychotic disorder, and a majority have histories of serious substance use.[5]

In this paper, we report on the prevalence of tuberculosis infection and selected risk factors for infection in a volunteer sample (n = 161) of homeless men who reside in a large congregate shelter (n = 660). We were particularly interested in exploring whether there might be a significant association between the length of stay in the shelter system and the development of tuberculosis infection, given that contagious spread is facilitated by living in overcrowded quarters.[6–8]

Methods

The Fort Washington Men's Shelter is located within a large armory administered by New York City's Human Resources Administration. The Shelter Medical Clinic, operated by Harlem Hospital Center, conducted the screening with the cooperation of the Harlem Hospital AIDS Treatment Group and the New York City Department of Health.

Approximately 660 men on a given night sleep in this shelter (see photo). Beds are separated by approximately 18 to 20 inches and are arranged on a large open floor measuring 55 000 square feet.

The drill floor (sleeping area) was selected as the screening site. Coffee and a snack were offered as an incentive for participation. Notices were posted throughout the shelter several days before the screening, and caseworkers who were in frequent contact with the men were encouraged to refer them to the screening. On November 26, 1990, 161 men volunteered and were evaluated for tuberculosis infection. Brief semistructured interviews were conducted. The date of the first shelter stay, which is entered into the Shelter Care Information Management System and signifies the date an individual was officially registered by a caseworker anywhere in the New York City shelter system, was used to approximate length of shelter stay.

A self-reported history of tuberculosis or a positive skin test in similar populations has been found to represent a valid assessment of tuberculosis status.[9–12] Therefore, all residents who did not have either a history of tubercu-

TABLE 1—History of Tuberculosis and Skin Test Reactions among Homeless Men in a New York City Shelter, 1990, by Age and Ethnicity (n = 134)[a]

	PPD Negative (n = 29)		PPD Positive by History (n = 33)		PPD Positive (n = 72)	
	n	%	n	%	n	%
Ethnicity						
African-American	22	75.9	22	66.7	60	83.3
Hispanic	7	24.1	11	33.3	12	16.7
Age, y						
20–29	9	31.0	9	27.3	27	37.5
30–39	16	55.2	15	45.4	25	34.7
40–49	4	13.8	6	18.2	14	19.4
50–61	0	0.0	3	9.1	6	8.3

Note. PPD = purified protein derivative.
[a]Excludes those who did not return for a reading (n = 24) or who were anergic (n = 3).

losis or a reactive skin test received (Aplisol) 5 tuberculin (0.1 mL) units of purified protein derivative injected intradermally in the volar aspect of the right forearm. Each resident also received anergy testing with 0.1 mL of 1:1000 strength Candida (in the left forearm). All tests were read within 48 to 96 hours and interpreted according to the American Thoracic Society's recommendations.[13] According to recommendations of the Centers for Disease Control and Prevention (CDC), a purified protein derivative reaction of 10 mm or greater of induration and a Candida reaction of greater than 2 mm of induration were interpreted as positive. Reactions of less than 10 mm were not recorded.

Results

Slightly more than three-fourths (77%) of the total sample (n = 161) identified themselves as African-American, 22% were Hispanic, and one respondent did not reveal his ethnicity. The mean age of the sample was 34.5 (SD = 8.6; range = 20 to 61 years). The mean length of time from date of shelter entry was found to be 31.8 months (SD = 18.6). Time since date of entry into the shelter system ranged from 0 months (2 weeks or less) to 8 years; the median was 29 months. Sixty-four percent of the total sample were defined as long-term users of the New York City shelter system, the criterion being a date of first shelter stay of more than 2 years ago.

TABLE 2—Risk of Tuberculosis Infection among Homeless Men in a New York City Shelter, 1990, by Age, Ethnicity, and Length of Shelter Stay

Predictor	Adjusted Odds Ratio[a]	95% Confidence Interval
Age, y	1.04	0.99, 1.11
African-American vs Hispanic	1.11	0.40, 3.13
Time from date of shelter entry, mo	1.02	1.00, 1.05

[a]Based on results of logistic regression model and adjusted for the other variables in the table.

TABLE 3—Predicted Probability of Tuberculosis Infection among Homeless Men in a New York City Shelter, 1990, by Time from Date of Shelter Entry[a]

	Months					
	0	6	12	18	24	36
Probability	.10	.12	.14	.16	.18	.24

[a]Based on results of logistic regression model.

Those men who were purified protein derivative positive by history and therefore were not tested at the screening represented 21% (n = 33) of the sample (see Table 1). One hundred twenty-eight participants were tested and 81.3% (n = 104) returned for a reading. Of those who returned, 69% (n = 72) were positive; three men failed to react to both purified protein derivative and Candida control. The mean induration value in millimeters for those who returned and tested positive was 18.8 (SD = 4.9, range 10 to 30). The breakdown in 5-mm increments was as follows: 10 to 14 mm: 16%; 15 to 19 mm: 35%; 20 to 24 mm: 35%; and 25 to 30 mm: 14%; only 21% were purified protein derivative negative.

The prevalence rate of any tuberculosis infection, including those participants with an induration of 10 mm or greater and those with past history, excluding the nonreturns, was 79%.

In a logistic regression predicting tuberculosis infection (based on past history or an induration of 10 mm or greater), time from date of entry into the shelter system was significantly associated ($P < .05$) with risk (Table 2). For example, control-

ling for age and ethnicity, the predicted probability of tuberculosis infection at 36 months from date of entry into the shelter system was .24 compared with only .14 at 12 months (Table 3).

Discussion

The most remarkable finding of this study was the extremely high prevalence, past or present, of tuberculosis infection (79%) among those who volunteered for screening. Also, it is notable that we, like others,[8] found that the length of shelter stay was significantly associated with the tuberculosis infection rate. These two findings support the proposition that crowded living conditions in congregate shelters are associated with the spread of tuberculosis infection.

Our study has some important limitations. First, the sample was self-selected and so potential selection bias was introduced. For example, caseworkers may have been more likely to refer medically ill clients to the screening or to have encouraged men at risk of tuberculosis infection (e.g., known intravenous drug users) to participate. However, we found no evidence of this bias.

Second, because an individual may not have stayed in the shelter continuously from entry date to date of screening, the length of shelter stay should be considered a proxy. Third, we had incomplete control of confounders, such as alcohol, drug use, and history of sexually transmitted disease and human immunodeficiency virus (HIV). Finally, only an induration of 10 mm or greater was interpreted as a positive test because, at the time of this screening, 10 mm was still what the CDC recommended for purified protein derivative test positivity in homeless individuals. Since the HIV status of the participants was unknown, 10 mm was used instead of 5 mm to capture all who would unquestionably be considered positive for purified protein derivative in this population. Given that this population is at high risk for HIV disease, one could speculate that the prevalence of purified protein derivative positivity was actually underrepresented since there may have been several men with an induration of between 5 and 9 mm. Based upon current CDC recommendations,[14] members of this group would be candidates for prophylaxis. Therefore, the rate of reported tuberculosis infection and implications for intervention may be even greater.

Local health departments can enable agencies to provide relatively safe tuberculosis-controlled living environments by mandating periodic tuberculosis screening and a follow-up chest x-ray and sputum analysis. Without an effective plan for follow-up, however, screening efforts will serve little purpose. Departments of Health must ensure that patients remain under medical supervision until treatment is completed. The recent epidemic of deaths due to multidrug-resistant tuberculosis strains reported in the New York metropolitan region[15] underscores the fatal consequences of episodic treatment of persons, especially those with immune deficiency. One might suspect that the costs of attempting to treat multidrug-resistant tuberculosis in terms of prolonged, recurrent hospitalization and possible surgery would far exceed those of using directly observed therapy, even with monetary incentives or the equivalent. However, for selected populations, especially among the disenfranchised, supervised therapy with incentives should be seriously considered. The eradication of tuberculosis will come about by social measures as well as by the development of better drugs and vaccines. □

The School-Based Immunization Survey: An Inexpensive Tool for Measuring Vaccine Coverage

ABSTRACT

A school-based immunization survey was conducted among the 36 Rochester, NY, elementary schools (n = 5584 children) to determine (1) the vaccination rates at 2 years of age by type of primary care provider and (2) the accuracy of school immunization records (by comparing them with medical charts for children attending hospital-based clinics). These rates varied by provider type from 58% to 86% and were all below the national goal of 90%. In comparison with medical chart review, the school data had error rates of 15%; however, these errors occurred in both directions and were thus unbiased. School-based surveys include children who lack connections to the primary care system. With minimal effort these surveys can help identify populations in need of intervention. (*Am J Public Health.* 1993;83:1749–1751)

Lance E. Rodewald, MD, Klaus J. Roghmann, PhD, Peter G. Szilagyi, MD, MPH, Nancy L. Winter, MPA, James R. Campbell, MD, and Sharon G. Humiston, MD, MPH

Introduction

School-based immunization surveys are frequently used to assess vaccination coverage for communities. Alternatives to such surveys have limitations. For example, random samples of children seldom provide enough data to determine vaccination levels of small areas such as neighborhoods served by schools. Immunization surveys of medical charts in providers' offices cannot assess vaccination levels of groups of interacting children because these children receive care from different providers. Schools, however, cover complete, interacting populations and keep comprehensive immunization histories of their students, even if vaccines are administered by multiple providers. The school-based immunization survey provides a unique and simple method to study vaccination rates of interacting populations.

In spite of these advantages, the methodology for school-based immunization surveys is not well described. Results of a few published surveys indicate low vaccination rates,[1–3] implying that many neighborhoods are at risk of outbreaks. However, little has been written on the methods of procedure, cost, strengths, and weaknesses of the school-based survey.[4] We report on an immunization survey of the Rochester, NY, City School District and discuss the methodological issues that pertain to data quality assurance.

Methods

Permission was obtained to analyze the immunization records of children beginning kindergarten in 1991 or 1992 in the Rochester City School District from the city school district, the Monroe County Department of Health, and the University of Rochester Research Subjects Review Board. All 36 city elementary schools participated in the project.

The following data were recorded: school attended, initials of the child, birth date, zip code, and primary care provider. The vaccines recorded were diphtheria, tetanus, and pertussis (DTP); oral polio vaccine (OPV); measles, mumps, and rubella (MMR); and *Hemophilus influenzae* type b (Hib). Inactivated poliovirus vaccine was recorded as OPV. Programs were written to re-create individual immunization histories into temporal sequence, calculate age-specific vaccination rates, and analyze these rates.

The following rates were calculated for each child: (1) those up to date for *all* vaccines at bimonthly intervals between 10 months and 72 months and (2) those up to date for *individual* vaccines by the same ages. The American Academy of Pediatrics *Red Book* recommendations were used to determine standard vaccination ages.[5] Specific algorithms, programs, and record abstraction forms are available from the authors.

The quality of the data was tested by two methods. First, inconsistent dates were identified and checked against the data entry form or against the original school record. Second, a random sample of charts that mentioned either of the two hospital-based pediatric continuity clinics as the student's primary provider was obtained. The charts were abstracted by using the same data collection forms; correlations between the school and provider records were determined.

Results

There were 2654 records abstracted for the 1990 to 1991 kindergartners and 2939 records abstracted for the 1991 to 1992 kindergartners, representing two birth cohorts of city school district children.

The authors are with the Department of Pediatrics, University of Rochester, Rochester, NY.

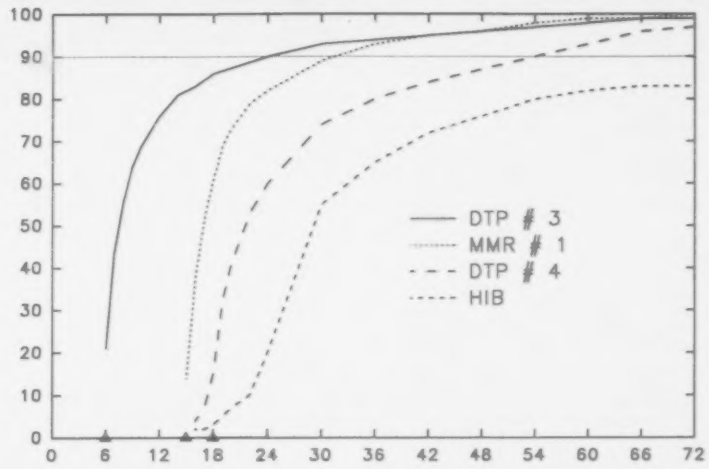
Note. DTP = diphtheria, tetanus, and pertussis; OPV = oral polio vaccine; MMR = measles, mumps, and rubella; Hib = *Hemophilus influenzae* type b.
[a]Required by New York State for school registration.
[b]Recommended by the American Academy of Pediatrics.



Note. DTP = diphtheria, tetanus, and pertussis; MMR = measles, mumps, and rubella; Hib = *Hemophilus influenzae* type b. The y axis shows the percentage of children who received the vaccine by the ages (in months) indicated on the x axis. The triangles indicate the recommended administration dates of the vaccines (6 months for DTP number 3, 15 months for MMR, and 18 months for DTP number 4 and Hib).

FIGURE 1—Pattern of receipt of selected vaccines.

Of the 2939 charts surveyed from the 1991 to 1992 class, 397 (13.5%) mentioned one of the two pediatric continuity clinics as the regular source of care. A sample of 171 charts, 97 from Strong Memorial Hospital and 74 from Rochester General Hospital, was drawn for cross checking. We tested for significant differences in vaccination rates between the samples drawn and the remainder (n = 226) and found none.

Because the survey did not use names, cross checks had to rely on matching by initials and date of birth. A chart not being found could be due to clerical reasons (name change, address change, or birth date inaccuracy) or to no chart being in the record room.

Of the 97 charts sought at Strong Memorial Hospital, 60 (62%) were located. Among these records, 766 immunizations were recorded in both the school survey and the medical record; 661 (86.3%) of these were identical in vaccine and date. The 105 (13.7%) vaccine discrepancies were as follows: 29 (3.8%) vaccinations were recorded in the school survey but not in the medical record, 40 (5.2%) were recorded in the medical record but not the school survey, and 36 (4.7%) had discrepancies in date of vaccination. Among the 36 discrepancies in dates, 14 were biased to make the school survey appear to have vaccines given at an older age and 22 were biased in the other direction.

Of the 74 charts sought at Rochester General Hospital, 54 (73%) were located. Among these records, 660 immunizations were recorded in both the school survey and the medical record; 562 (85.2%) of these were identical in vaccine and date. The 98 (14.8%) vaccine discrepancies were as follows: 37 (5.6%) vaccinations were recorded in the school survey but not in the medical record, 33 (5.0%) were recorded in the medical record but not the school survey, and 28 (4.2%) had discrepancies in date of vaccination. Among the 28 discrepancies in dates, 13 were biased to make the school survey appear to have vaccines given at an older age and 15 were biased in the other direction.

We then checked for differences in vaccination status between the school records found and those not found at the two continuity clinics. At the Rochester General Hospital clinic, no statistically significant differences were found. At the Strong Memorial Hospital clinic, however, where fewer charts could be located, we found that children with locatable charts had higher vaccination rates than did children for whom no chart could be found. We could not determine whether the primary care provider was not listed correctly for these children or whether one of the variables used to match the school record with the medical chart was incorrect.

Table 1 shows the number of specific vaccinations per child for both survey years, and Figure 1 shows the pattern of receipt of selected individual vaccines. It can be seen that 18 months from the recommended administration date[5] were required to achieve a 90% vaccination rate for DTP number 3. Similarly, 90% vaccination rates required 36 months for DTP number 4 and 15 months for MMR. A 90% vaccination rate was not attained for the Hib vaccine. The mean length of time necessary to achieve 90% vaccination rates for DTP numbers 1 through 4 and MMR was 14.2 months.

Discussion

School-based immunization surveys gather patient-level details about vaccination histories during the preschool years of life, the time when children are most vulnerable to vaccine-preventable diseases.[6,7] We have shown that these vaccination histories can be reconstructed in a simple computer database to facilitate the calculation of several measures of vaccination status.[8]

Error in school-based immunization survey data can be introduced at several levels, most perniciously by inaccurate or incomplete recording of dates by school officials. Such error would lower calculated rates. Our data suggest that relative to medical chart review, error occurred in both directions and was therefore unbiased.

This survey methodology is not only powerful but inexpensive. The entire sur-

vey was conducted in a 3-week period by three chart abstractors. Once permission is obtained to survey the school district, the actual implementation of the survey is not difficult. The algorithms for measuring vaccination rates are straightforward and can be encoded in either database or statistical package languages.

Because school-based data include children who have no identified provider or who change providers, these surveys are useful for identifying groups of children who may lack connections to the primary care system. Because these children are at the highest risk of adverse outcome, inadequate screening for disease, and inadequate vaccination, this methodology can potentially identify targets for interventions. In contrast, provider-based surveys cannot identify children with inadequate access to the primary care system. A characteristic of school-based immunization surveys, however, is that the surveyed population consists of those children who remain in the city and attend a city school. Migration from the city will reduce the survey scope as a result of omission of those children who were city residents during their preschool years but who moved to the suburbs by school entry. Busing children into or out of the school district will also complicate the survey.

Closing the "toddler gap" in vaccination services will probably require a multifaceted approach. One of the essential early steps is to obtain data that can help to target interventions accurately. Retrospective school-based immunization surveys can provide those data in a short period of time and with minimum effort. □

The Impact of a Public Health Nurse Intervention on Influenza Vaccine Acceptance

Margaret E. Black, MSN, Jenny Ploeg, MScN, Stephen D. Walter, PhD, ARCS, Brian G. Hutchison, MD, MSc, CCFP, E. A. Fran Scott, MD, MSc, CCFP, FRCP, and Larry W. Chambers, PhD, MSc

ABSTRACT

Public health clients in an Ontario community 65 years of age or older were randomly allocated to receive an intervention by a public health nurse during a home visit promoting either influenza immunization or safety measures. There was no statistically significant difference in influenza immunization rates between these two groups (56.1% vs 56.6%). Men were significantly more likely to receive immunization. (*Am J Public Health.* 1993;83:1751–1753)

Introduction

Annual vaccination against influenza is currently recommended for all persons 65 years of age or older.[1–4] Despite this recommendation, vaccination rates among community-living North American seniors remain at approximately 20% to 30%.[5–7] The literature suggests that structured personalized communication[8–14] using components of the health belief model and expectancy-value theory offers considerable promise in altering health behaviors. The current lack of incentives for primary care physicians to promote vaccination and the positive experience in nurse-led interventions[15–17] provide encouragement for the development of a public health nurse intervention.

Reported talking about immunization with public health nurse	42.2	18.2	24.0 (13.9, 31.9)

Methods

Research Design and Setting

Public health clients were randomly assigned to receive a public health nurse intervention during a home visit promoting either influenza immunization (study group) or safety measures (control group). The study took place in an urban–rural region of 450 000 residents, 13.3% of whom were 65 years of age or older.[18]

All 1011 clients aged 65 years or older who were considered active clients as of August 1990 or were referred to public health between September 1, 1990, and January 15, 1992, were randomly assigned to one of two groups. They were visited or contacted by 1 of the 18 seniors program public health nurses to determine, during the course of their usual care, whether they were eligible and willing to participate in the study. If it was determined that the client and/or proxy (family or close friend) were not able to or could or would not participate, the public health nurse did not proceed with the promotion and the client was therefore not part of the study. Some clients required more than one visit for the promotion. The public health nurses were instructed to provide their "usual care" regarding the topic of the alternate promotion.

The influenza promotion was designed to be individualized to address each client's unique concerns. The public health nurse reviewed influenza and its vaccine with clients and identified strategies to overcome barriers to immunization by family physicians (e.g., transportation services available in the community).

Data Collection

Outcome data were obtained through telephone interview (or home visit) by two research assistants who were unaware of group membership. Assignment of clients to research assistants was randomized. All clients were asked identical questions regarding the receipt of influenza immunization, self-rated health, and the presence of high-risk conditions[19,20] (heart disease, respiratory disease, or diabetes). Clients who did not receive the immunization were asked to explain their reasons. Both client groups were asked safety questions.

Results

Of the 1011 potential study clients, 589 (58.0%) were excluded for reasons such as cognitive impairment and "inactive" client status. An additional 57 clients (5.6%) refused the promotion, and 6 (0.6%) were lost to follow-up. Of those who were recruited, 157 received the influenza promotion and 148 received the safety promotion. Another 45 clients had been assigned to the influenza group but did not receive the promotion because the public health nurse found that they had already been administered influenza vaccine. These 45 subjects and those who were missed (n = 9) were included in the analysis in their originally allocated group (an "intention to treat"[21] analysis); thus, a total sample of 359 was analyzed.

Among these 359 clients, 117 were men and 242 were women; the mean age was 77.2 years. The sex and age distributions were very similar in the two groups (see Table 1). No between-group differences were found in the proportion of subjects reporting at least one chronic health condition or receiving the alternate promotion together with the assigned promotion. The mean ratings of self-rated health were similar.

At follow-up, there were no differences between groups in the number of subjects interviewed through a proxy, the number assigned to the two interviewers, and the number deceased. Also, there were no statistically significant differences in the rates of self-reported influenza immunization in the influenza and safety groups (56.1% and 56.6%, respectively) (see Table 2).

A post hoc power analysis confirmed that the sample size was sufficient to have detected a 50% relative increase in the vaccination rate (80% power, 5% alpha, two-sided). After the effects of the presence of chronic health conditions, self-rated health, and sex were controlled, there was still no statistically significant difference between the group immunization rates. In a pooled analysis of both study groups, we found that men were more likely than women to receive influenza immunization (70.5% and 49.6%, respectively).

Multiple logistic regression was used to examine the relative contribution of sex, promotion group, age, chronic health conditions, self-rated health, public health nurse, and public health nurse experience on the likelihood of receiving the influenza immunization. Even when group membership was forced into the model, only the effect of sex was significantly associated with the likelihood of receiving immunization when all of the variables were considered simultaneously ($\beta = .89$ [SE] .25), $P < .003$, 95% CI = 1.51, 4.01).

Forty-nine clients (33.7% and 45.7% of the nonvaccinated clients in the influenza and safety groups, respectively) gave reasons for not receiving immunization. The three most frequent reasons in the influenza promotion group were forgetting/confusion, prior experience with vaccine side effects, and beliefs regarding immuni-

zation. In the safety group, the most frequent reasons were beliefs regarding immunization and previous experience with vaccine side effects.

Discussion

The immunization rates reported here were considerably higher than the expected community rates of 20% to 30% for older persons.[5–7] Because of the nature of public health referrals, our subjects may be more likely to see a physician regularly and may be perceived as at greater risk; therefore, they may be more likely to be offered immunization. However, because there are no recent surveys on immunization rates among older adults in our community, we cannot be certain of the extent to which this subgroup is representative of the older community in general.

The reasons clients reported for failing to receive immunization were consistent with those previously reported[14,22] and appear to be an important barrier to preventive behavior. In contrast to findings reported by Conn,[23] the presence of chronic health conditions and self-rated health were not related to immunization behavior in this study.

Our finding that men were more likely than women to receive immunization was puzzling. Future studies could investigate population- and sex-specific influenza immunization rates. Researchers could also examine the effect of peer support in overcoming the reluctance of those whose beliefs constitute barriers to vaccine acceptance. Finally, qualitative research methods may contribute to our understanding of older clients' perceptions and their willingness to participate in preventive self-care. □

Neonatal Tetanus in Peru: Risk Assessment with Modified Enzyme-Linked Immunosorbent Assay and Toxoid Skin Test

Louis Vernacchio, BA, Guillermo Madico, MD, Manuela Verastegui, MS, Fernando Diaz, MD, Timothy S. Collins, BA, and Robert H. Gilman, MD

ABSTRACT

We used a modified enzyme-linked immunosorbent assay (ELISA) to investigate tetanus immunity in 232 pregnant Peruvian women. One hundred forty-two (61.2%) had protective antitoxin titers (≥0.01 IU/mL). Protective titers correlated positively with the number of toxoid doses reported during the current pregnancy. A majority of women reporting no toxoid doses during the current pregnancy had at least one prenatal health care visit. We evaluated a toxoid skin test in 44 of the subjects, but it correlated poorly with the ELISA. The modified ELISA is a useful in vitro method for studying tetanus immunity in the developing world. (*Am J Public Health.* 1993;83:1754–1756)

Introduction

Neonatal tetanus causes over 780 000 deaths worldwide each year.[1] Peru reports approximately 0.4 cases per 1000 live births, one of the highest rates in Latin America.[2] Yet adequate maternal immunization with tetanus toxoid can completely prevent the disease.[3,4] During pregnancy, two adequately spaced injections of tetanus toxoid induce protective levels of antitoxin in more than 80% of previously unimmunized women, and three injections protect virtually 100%.[5,6]

Antitetanus vaccination efforts in the Third World have failed to reach large numbers of women of childbearing age. No information on the success of such efforts in Peru has been published.

Serologic investigation of tetanus immunity in the developing world presents several problems. The gold standard mouse neutralization assay is costly and cumbersome. Routine use of the enzyme-linked immunosorbent assay (ELISA) and hemagglutination have proven unreliable for measuring low titers.[7,8] Simonsen et al. have developed a modified competitive ELISA that correlates extremely well with the in vivo standard.[9] This recently developed in vitro assay has not been used to study tetanus immunity in a Third World population.

Even with the modified ELISA, large-scale studies of tetanus immunity in the developing world remain difficult. Intradermal injections of tetanus toxoid elicit a delayed hypersensitivity reaction in a large percentage of previously immunized subjects, and this reaction may correlate with serum antitoxin titer.[10,11] A reliable skin test would greatly facilitate the study of tetanus immunity.

We designed a study to assess serum tetanus antitoxin levels in pregnant Peruvian women with the modified ELISA. We administered a tetanus toxoid skin test to a subset of our subjects to investigate its use as a screen for tetanus immunity.

Subjects and Methods

Subjects

Subjects were pregnant women presenting in labor to three hospitals: Cayetano Heredia, serving a poor and lower-middle-class population in Lima; Maternidad de Lima, a large maternity hospital serving poor women from Lima and its shantytowns; and Hospital Regional del Amazonas in the city of Iquitos in the Amazon jungle.

Women admitted in labor to these hospitals during the study period were enrolled. Verbal consent was obtained. Subjects were interviewed about antitetanus vaccination during their current pregnancy. A blood specimen was obtained by venipuncture. A tetanus toxoid skin test was performed on a subset of the subjects.

ELISA

The modified ELISA was performed according to Simonsen et al.[9]

Skin Test

A 0.1-mL dose of vaccine-grade adsorbed tetanus toxoid (Connaught) was injected intradermally on the anterior aspect of the forearm. Reactions were scored as the greatest diameter of induration at 36 to 72 hours. A positive cutoff of 5 mm or more was chosen.

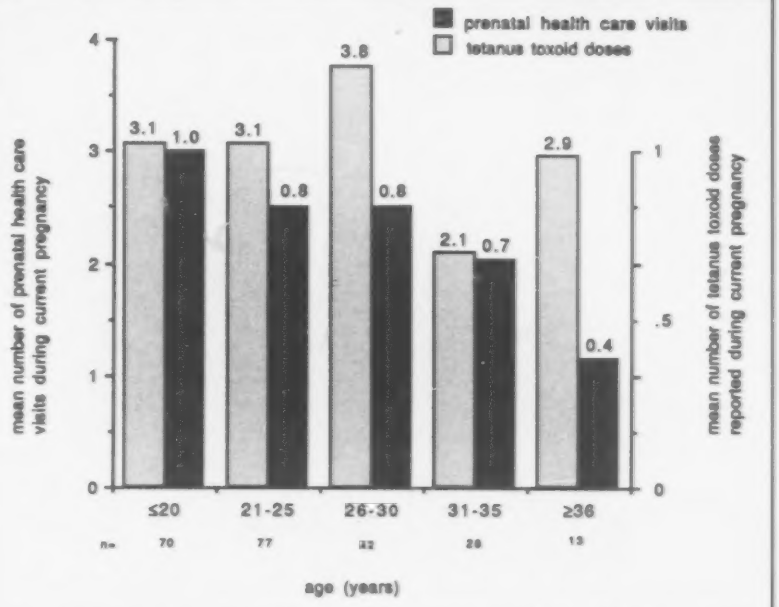
TABLE 1—Percentage of Subjects with Protective Serum Tetanus Antitoxin Levels, by Hospital

Hospital (Location)	No. Subjects	Subjects with Protective Antitoxin Level (≥ 0.01 IU/mL),[a] %
Maternidad (capital)	141	58.2
Cayetano (capital)	21	71.4
Amazonas (jungle)	70	64.3
Total	232	61.2

[a] $P = 0.42$, chi-square test, for comparison among hospitals.



Note. n = 230 because prenatal health care data were not available for two subjects. Prenatal healthcare visits, $P = .69$, linear regression analysis; tetanus toxoid doses, $P = .027$, linear regression analysis.

FIGURE 1—Mean number of prenatal health care visits and mean number of tetanus toxoid doses reported during the current pregnancy, by age group.

Results

A total of 232 pregnant women in labor (mean age ± SD = 24.5 ± 5.9 years) were included in the study. The number of pregnancies (including the current one) ranged from 1 to 10 (median = 2; 10th and 90th percentiles = 1 and 6). Subjects reported a mean of 3.1 (SD = 3.0) prenatal health visits and a mean of 0.9 (SD = 0.9, range = 0–3) tetanus toxoid injections during the current pregnancy.

A total of 142 of 232 (61.2%) subjects had a serum tetanus antitoxin concentration above the protective level of 0.01 IU/mL. No difference was found among hospitals ($P = .42$, chi-square test; Table 1).

Of the subjects reporting 0, 1, 2, and 3 tetanus toxoid injections during the index pregnancy, 39.6%, 71.7%, 87.3%, and 100%, respectively, had a protective serum antitoxin level ($P < .00001$, chi-square test for linear trend). Both the percentage of subjects with positive titers and the number of tetanus toxoid doses reported during the pregnancy decreased with increasing age group ($P = .00036$, chi-square test for linear trend [positive titers]; $P = .027$, linear regression analysis [tetanus toxoid doses]), but we found no relationship between age and the number of prenatal health care visits ($P = .69$, linear regression analysis; Figure 1).

Of the subjects who reported receiving no tetanus toxoid injections during the pregnancy, 55 of 106 (51.9%) gave a history of at least one prenatal health care visit and 49 of 106 (46.2%) gave a history of two or more such visits. Of those reporting only one injection, 39 of 60 (65.0%) reported at least two prenatal health care visits.

Tetanus toxoid skin tests were administered to 70 subjects. Twenty-six tests (37.1%) were not read because the subject was discharged less than 36 hours after placement. Of the 44 skin tests read, 18 (40.9%) were positive, but the test correlated poorly with the modified ELISA, with a sensitivity of 57.7% and a specificity of 83.3% (Figure 2).

Discussion

The modified ELISA developed by Simonsen et al.[9] was useful for studying tetanus immunity in a developing country and provides an alternative to the standard in vivo assay.

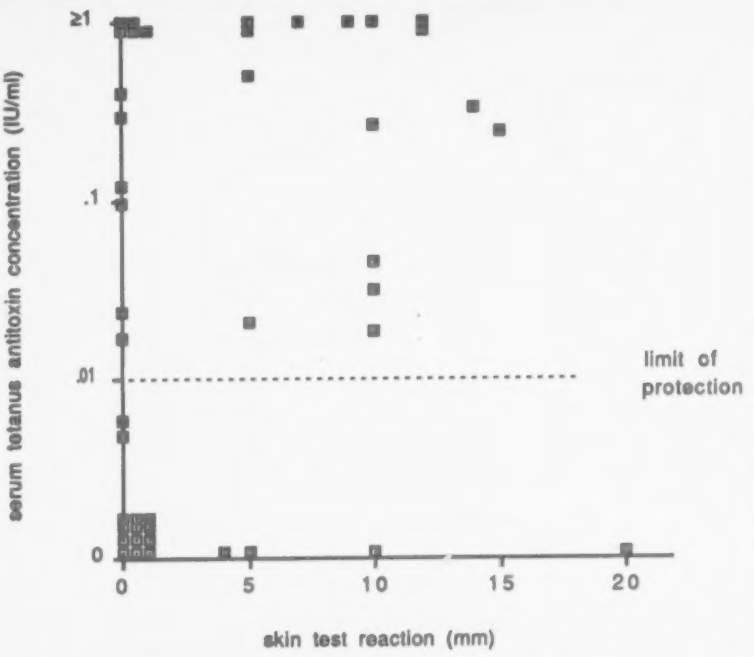
Roughly 40% of hospitalized pregnant Peruvian women lack sufficient serum tetanus antitoxin to protect their newborns against neonatal tetanus. That the rate in a jungle hospital was comparable to that of two Lima hospitals probably reflects recent vaccination efforts to target the jungle region of Peru, an area traditionally endemic for tetanus.

The overall 60% rate of protection exceeds the 1990 World Health Organization estimate of 29% for pregnant women in the developing world.[1] Our survey is, however, limited to hospitalized women. We would expect the coverage among women giving birth outside of hospitals to be lower owing to decreased access to health care.

A striking finding of our study was that a large percentage of women receiving no tetanus toxoid injections during their pregnancy reported one and often more prenatal health care visits. Clearly, many opportunities for vaccination were missed in our study population.

Our results confirm the highly significant correlation between the number of tetanus toxoid doses during pregnancy and the protective antitoxin titers. Among those subjects reporting two or three vaccinations during the pregnancy, almost 90% had protective antibody titers. Yet 40% of the subjects reporting no vaccinations during the pregnancy nevertheless had protective titers. Their immunity may represent either previous vaccination or naturally acquired antibody. Data from India and Brazil indicate that 3% to 40% of nonvaccinated subjects have positive antitoxin titers.[12–14] These findings suggest that health care workers can accept a patient's report of recent vaccinations, although a report of no recent vaccinations does not rule out immunity.

Younger women in our study were vaccinated more frequently than older women. Because we found no relation-



Note. Minimum positive skin test reaction was ≥5 mm: sensitivity, 57.7%; specificity, 83.3%. $R = .161$; $P = .30$, linear regression analysis.

FIGURE 2—Serum tetanus antitoxin level as determined by the modified ELISA vs the maximum diameter of induration with the tetanus toxoid skin test.

ship between age and the number of prenatal health care visits, the younger women either were offered vaccination more frequently or accepted it more often.

The tetanus toxoid skin test was of little value as a predictor of tetanus immunity. Factors responsible for the many false-negative results may include a decrease in cellular immune response to specific antigens in pregnant women near term[15,16] and the time period between vaccination and skin testing.

Neonatal tetanus remains an important cause of neonatal mortality in the developing world. Even in a population of Peruvian women with access to health care, tetanus vaccination rates remain far from ideal. Further studies to determine the reasons for missed vaccination opportunities would be helpful.

The modified ELISA was useful for investigating tetanus immunity in a developing country. Its wider application would facilitate study of other Third World populations. □

HIV Transmission: Women's Risk from Bisexual Men

Robert W. Wood, MD, Leigh E. Krueger, MPH, Tsilke C. Pearlman, and Gary Goldbaum, MD, MPH

ABSTRACT

The purpose of this study was to characterize the risk of human immunodeficiency virus (HIV) infection for men who have sex with men and to identify the risk such men pose to their female sex partners. The subjects were 5480 men who were tested for HIV between January 1987 and December 1991 and who reported having had sex with a man since 1977. Men who identified themselves as bisexual or straight were more likely to use injection drugs, had a substantial HIV seroprevalence, and reported many more female partners than men who identified themselves as gay. Men who identify themselves as bisexual pose the greatest risk to their female partners. (*Am J Public Health.* 1993;83:1757–1759)

Introduction

A recent analysis of national acquired immunodeficiency syndrome (AIDS) surveillance data indicated that men who reported having sex with both men and women (bisexuals) differed from those who reported having sex only with men (homosexuals) in important ways.[1] Although two thirds (67%) of women with heterosexually acquired AIDS (excluding women born in the Caribbean or Africa) reported that their sex partner was an injection drug user,[2] 11% reported sex with a bisexual man as their only risk.[1] Because bisexual men are increasingly likely to contribute to human immunodeficiency virus (HIV) infections in women,[1,3–6] we sought to further characterize the risk of HIV infection for men who have sex with men and to identify the risk such men pose to women.

Methods

The AIDS Prevention Project of the Seattle–King County Department of Public Health actively recruits for HIV counseling and testing persons at highest risk for HIV. Although the Project accounts for only 23% of the HIV testing performed at the Seattle–King County Department of Public Health, it identifies more seropositive persons than all other Department clinics combined (203 of 352 [58%] in 1991).

Trained staff collect standard demographic, medical, and risk data on all persons seeking HIV counseling and testing, including the number of male and female sex partners during the previous 12 months, self-stated sexual identity ("gay," "bisexual," "straight"), specific sexual practices and condom use, and other risks for HIV infection, including injection drug use. For HIV testing, blood undergoes enzyme immunoassay analysis (LAV EIA, Genetic Systems, Seattle, Wash),[7] which is repeated if reactive and confirmed by indirect fluorescence assay (VIRGO HIV IFA, Pharmacia Diagnostics, Inc, Columbia, Md)[8] or Western blot (Biotech/DuPont HIV-1 Western Blot Kit, Ortho Diagnostic Systems Inc, Raritan, NJ) analysis.[9]

We analyzed cross-sectional data from each subject's latest clinic visit between January 1987 and December 1991. The subjects were 5480 men who reported having sex with another man since 1977 and who elected to undergo HIV testing following pretest counseling. (Only 3.2% of men counseled elected not to test.) We analyzed data separately for HIV-infected men, whether or not they reported having sex during the previous year, and uninfected men who reported having sex with both men and women in the past year.

For categorical data we calculated the chi-square or Fisher's Exact Test, plus odds ratios with 95% confidence intervals.[10] Differences are considered significant if $P < .05$.

Results

Self-reported sexual identity was an important predictor of having sex with women and of HIV seropositivity at our site. Of the 5480 subjects, 77% identified themselves as gay and reported almost no sex with women in the previous year (average 0.07 female partners); 13% identified themselves as bisexual (average 1.4 female partners); and 8.4% identified themselves as straight (average 2.7 female partners). Men who self-identified as gay had the highest HIV seroprevalence (27%); however, substantial numbers of those who said they were bisexual or straight were also infected (12% and 8%, respectively).

Injection drug use was reported by 11% of the gay men, 20% of the bisexual men, and 34% of the straight men ($P < .05$). Injection drug users reported

TABLE 1—HIV Seroprevalence by Sexual Identity, and Exposure of Female Partners by HIV-Infected Men Who Have Sex With Men: Seattle, Wash, 1987 through 1991

	n	HIV Prevalence, %	HIV-Infected Men with Female Partners		
			No. Men	%[a]	Total No. Female Partners
"Straight" men	457	7.7	12	34.3	32
Non-IDUs	303	7.6	4	17.4	5
IDUs	154	7.8	8	66.7	27
"Bisexual" men	711	12.4	31	35.2	116
Non-IDUs	567	9.5	15	27.8	38
IDUs	144	23.6	16	47.1	78
"Gay" men	4226	26.6	18	1.6	32
Non-IDUs	3772	24.5	12	1.3	22
IDUs	454	44.5	6	3.0	10
Total	5480	23.0	63	5.0	182
Non-IDUs	4712	21.4	32	3.2	66
IDUs	768	33.1	31	12.2	116

Note. IDU = injection drug user. The table totals include data on 86 persons (16 IDUs) who did not specify their sexual identity.
[a]Percentages are based on seropositive men.

TABLE 2—Number of Sex Partners of Uninfected Bisexually Active Men in the Preceding 12 Months, by Stated Sexual Identity and Injection Drug Use

	n	Mean No. Partners per Subject	
		Female	Male
"Straight" men	70	3.8	2.8
Non-IDUs	52	3.0	2.0
IDUs	18	6.1	5.3
"Bisexual" men	277	2.6	7.9
Non-IDUs	222	2.0	6.5
IDUs	55	4.8	13.6
"Gay" men	86	2.3	9.9
Non-IDUs	76	2.3	10.0
IDUs	10	2.2	9.4
Total	451	2.8	7.7
Non-IDUs	363	2.2	6.8
IDUs	88	4.9	11.5

Note. IDU = injection drug user.

having more female sex partners during the previous 12 months (mean 1.5) than did those who did not report injection drug use (mean 0.3). Injection drug users were also more likely than nonusers to be HIV-infected (33% vs 21%) (odds ratio [OR] = 1.8, 95% confidence interval [CI] = 1.5, 2.2).

Of the seropositive men, most (89%) identified themselves as gay, but most (81%) of the female partners exposed in the previous year were exposed by straight and bisexual men (Table 1). Significantly more injection drug users than nonusers reported having female partners (OR = 4.2, 95% CI = 2.4, 7.4). Eleven (17%) of 63 HIV seropositive men reported always using condoms for vaginal sex during the previous 6 months; 15 (24%) reported having only unprotected vaginal sex. Injection drug users were more likely than nonusers to report having unprotected vaginal sex, a nonsignificant difference.

Of the 451 HIV-seronegative men who reported having had both male and female partners in the previous year, almost two thirds (277, or 61%) identified themselves as bisexual (Table 2). Although only one in five (20%) of these men were injection drug users, those who were injection drug users averaged more than twice as many female sex partners as the seronegative bisexual men who did not use injection drugs. These bisexual men reported always using condoms only 12% of the time, and 30% reported never using condoms. Injection drug users did not differ from nonusers in their use of condoms.

Discussion

Compared with men who identified themselves as gay or bisexual, straight-identified men who have sex with men reported having more female sex partners and fewer male partners during the preceding year, and they were less likely to be HIV-infected. Even so, HIV seroprevalence among straight-identified men who have sex with men was remarkably high (8%), although lower than in bisexual men (12%). Straight men reported almost twice as many female sexual partners as bisexual men and 38 times as many female partners as gay men. Men who identified themselves as bisexual exposed the most women to HIV infection in the previous 12 months; gay and straight men exposed equal numbers of women. Women's risk is greatest from self-identified bisexual men. Men who have sex with men, both HIV seropositive and seronegative, had a low rate of consistent condom use during vaginal sex (12%).

Our conclusions pertain to Seattle men who have sex with men seeking HIV counseling and testing at an AIDS prevention program and may not reflect the population of men who have sex with men at large. Although a fifth of our subjects identified themselves as straight or as bisexual, this proportion could be too low if straight-identified men who have sex with men are reluctant to come to a gay-oriented AIDS clinic or do not perceive themselves to be at risk for HIV infection. Recruiting such men may require different strategies.[11]

Sexual self-identification may be a geographically variable phenomenon; our findings should be studied in other locales. Reporting biases might result if gay men underreport female partners or bisexual or straight men overreport them. Interviewer biases (since some are gay and more attuned to gay men) could result in incomplete ascertainment of female partners (and their risk). The use of standard protocols for interviews and data recording, however, should reduce this source of bias.

As others have noted,[1] the population of men who have sex with men but do not identify themselves as gay is in great need of further study to determine its size, its risks for further HIV transmission, and the best intervention methods. In the meantime, it appears that increased attention should focus on men who have sex with men and who also use injection drugs. □

Acknowledgments

This study was supported by the AIDS Prevention Project, Seattle–King County Department of Public Health.

Acculturation and Gender Differences in Sexual Attitudes and Behaviors: Hispanic vs Non-Hispanic White Unmarried Adults

Barbara VanOss Marín, PhD, Jeanne M. Tschann, PhD, Cynthia A. Gómez, PhD, and Susan M. Kegeles, PhD

ABSTRACT

Understanding how acculturation and gender affect Hispanics' sexual behavior is needed to prevent infection with the human immunodeficiency virus. We examined differences in and correlates of condom use among 398 Hispanics and 540 non-Hispanic Whites in San Francisco who were part of a random probability sample of unmarried adults. Hispanic women reported fewer sexual partners than all other groups. Condom use was low in all groups, but Spanish-speaking Hispanic women reported lower condom use than White women. Hispanics, generally, had poorer attitudes toward condoms and were less likely than non-Hispanic Whites to believe they could avoid acquired immunodeficiency syndrome. Hispanics need targeted prevention interventions. (*Am J Public Health.* 1993;83: 1759–1761)

Introduction

In the United States, acquired immunodeficiency syndrome (AIDS), the human immunodeficiency virus (HIV), and sexually transmitted diseases are disproportionately found in Hispanic populations.[1–4] Thus, models for understanding sexual risk behaviors among these populations are urgently needed.

Culturally appropriate programs must be based on a clear understanding of the antecedents of risk behaviors.[5,6] Among Hispanics, acculturation—a process of adaptation in which immigrants alter their attitudes and behaviors to more closely resemble those of the host society—is an important predictor of many health-related behaviors, including cigarette smoking, alcohol use, and early sexual initiation.[7–9] For certain behaviors, such as smoking and drinking, acculturation affects each gender differently, making women more likely to adopt risky behaviors but not men.[8,9] Given the traditional attitudes toward gender roles reported among less acculturated Hispanics,[10] gender and acculturation should be important factors in understanding sexual behavior among Hispanics.

The present study sought to identify ethnic, acculturative, and gender differences both in the number of sexual partners and in condom attitudes and behaviors among a random sample of young unmarried Hispanic and non-Hispanic White adults in San Francisco.

Methods

Respondents

In total, 1770 respondents were interviewed from 1988 to 1989 for a research project, the AIDS in Multiethnic Neigh-

[a]Scores were derived from the following scale: never = 1, sometimes = 2, and always = 3.
[b]Tukey post hoc comparisons show this group to differ significantly from all other groups.

borhoods Study. This paper reports on 938 respondents who reported no homosexual or bisexual behavior in the 12 months prior to the interview and who self-identified as either Hispanic (n = 398) or White (n = 540). Table 1 reports the demographics of this sample.

Procedure

A complete description of the rationale for target population selection, sampling methods, and participation rates for the research appears elsewhere.[11] Briefly, the target population consisted of currently unmarried men and women, aged 20 to 44, who lived in 16 census tracts of San Francisco. Each household had the same probability of being selected (1 in 6.2). All eligible respondents in the household were interviewed. The response rate was 64%.

The interview included a detailed assessment of sexual behavior in the previous 12 months, a variety of attitudinal measures, and demographic items. Acculturation was not measured directly, but the language spoken in the interview was used as a reasonable proxy.[12,13] The instrument was translated into Spanish using a back-translation procedure.[14]

Statistical Analysis

A series of 3×2 analyses of covariance were conducted, with ethnicity/language and gender as independent variables, and age, education, and income as covariates. The first analysis included all respondents and used partner type (not sexually active; monogamous, long term; monogamous, less than 1 year; and multiple partnered) as the dependent variable. Additional analyses of covariance were based on sexually active respondents only and used condom use (always, sometimes, or never with all partners), condom attitude, or beliefs about avoiding AIDS as the dependent variable.

Results

Ethnic/Language and Gender Differences in Sexual Behavior

Partner type. Overall, 18% (n = 165) of respondents were not sexually active in the past year, 35% (n = 324) were monogamous with no new partner, 10% (n = 90) were monogamous with a new partner, and 38% (n = 359) had multiple partners. Ethnicity/language (F [2, 915] = 16.37, $P < .001$), gender (F [1, 915] = 30.45, $P < .001$), and their interaction (F [2, 915] = 7.33, $P < .001$) are all significant predictors of partner type (see Table 2).

Condom use. Condom use was low: among the 773 sexually active respondents, 58% (n = 452) reported never using condoms, 33% (n = 255) reported sometimes using condoms, and 9% (n = 66) reported always using condoms. Only the interaction between ethnicity/language and gender is significant (F [2, 755] = 3.12, $P < .05$) (see Table 3).

Ethnic/Language and Gender Differences in Psychological Variables

Condom attitude. Women had more positive attitudes about condom use than men (F [1, 764] = 35.80, $P < .0001$), and non-Hispanic Whites had more positive attitudes than Spanish-speaking Hispanics (F [2, 764] = 4.43, $P < .02$). The interaction between ethnicity/language and gender is not significant (see Table 4).

Beliefs about avoiding AIDS. Spanish-speaking Hispanics had the lowest belief that they could do something to avoid AIDS (F [2, 764] = 68.54, $P < .0001$). Women had higher scores than men (F [1, 764] = 11.02, $P < .001$). The interaction between ethnicity/language and gender is not significant (see Table 4).

TABLE 4—Attitudinal Variables for Each Gender and Each Ethnicity and Language Group among Sexually Active Respondents

	Men (n = 415)	Women (n = 358)	Non-Hispanic Whites (n = 483)	English-Speaking Hispanics (n = 147)	Spanish-Speaking Hispanics (n = 143)
Condom attitude[a,b]	2.2	2.5	2.4	2.5	2.1
Beliefs about avoiding AIDS[a,c]	3.4	3.6	3.7	3.5	2.8

[a]Values correspond to mean scores.
[b]Condom attitude included the following: vaginal intercourse is enjoyable with condoms, condoms take the fun out of sex, sex doesn't feel as good with condoms, and condoms are physically uncomfortable to use. Range: 1 to 5, with higher scores indicating more positive attitudes.
[c]Beliefs about avoiding AIDS included the following: little can be done if one's partner does not want to use condoms, and little can be done to avoid AIDS. Range: 1 to 4, with higher scores representing stronger beliefs that one can avoid AIDS.

Discussion

Unmarried Hispanic women reported fewer partners than unmarried Hispanic men or unmarried non-Hispanic White men and women. On the other hand, more than one third of the Spanish-speaking Hispanic men and almost half of the English-speaking Hispanic men in this study reported having multiple partners. In traditional Hispanic culture, such "macho" behavior is expected of a man.[10,15,16] Accordingly, it is often erroneous for a Hispanic woman with only one partner to consider herself at low risk. Moreover, among sexually active respondents, Spanish-speaking Hispanic women had the lowest rates of condom use. Thus, Hispanic women can be seen as both more protected and more at risk; although they reported lower sexual activity, those who were sexually active had lower rates of condom use while their male counterparts reported high rates of multiple partners. These findings form part of a larger context in which Spanish-speaking women are less knowledgeable about HIV in general than non-Hispanic White women,[17] carry condoms less often,[18] and see condoms as unpleasureable.

In this study, men were more likely than women to view condoms as interfering with their sexual pleasure. Respondents were fairly negative about condoms, with men, and particularly Spanish-speaking men, being most negative. Both Spanish-speaking men and women believed there was little they could do to avoid AIDS. This suggests the need for special campaigns in Spanish to address these beliefs.

This random sample of unmarried adults drawn from 16 census tracts in San Francisco may be representative particularly of Hispanic and non-Hispanic Whites who are young, unmarried, and living in urban areas. However, generalization to Hispanic subgroups other than Mexicans and Central Americans should be done with caution.

AIDS-related attitudes and behaviors are strongly associated with gender, ethnic group, and level of acculturation. Traditional Hispanic culture may pose particular challenges to AIDS prevention educators, especially to those attempting to reach and influence less acculturated Hispanic women. □

Inappropriate Halsted Mastectomy and Patient Volume in Italian Hospitals

Roberto Grilli, MD, Franco Mainini, MD, Angelo Penna, MD, Guido Bertolini, MD, Nicola Scorpiglione, MD, Valter Torri, MD, and Alessandro Liberati, MD

ABSTRACT

To study whether Halsted mastectomy was used only when properly indicated, a prospective survey was undertaken on the process of care of 985 breast cancer patients seen consecutively at 62 general hospitals in Northern and Central Italy. Overall, 79% of Halsted mastectomies were performed inappropriately. The procedure was less likely to be performed on more educated patients and, other factors considered, on those seen at hospitals with larger volume. We conclude that the measurement of utilization of a surgical procedure for which only a few appropriate indications exist may help identify important relationships between hospital characteristics and quality of surgical care. (*Am J Public Health.* 1993;83:1762–1764)

Introduction

A few studies have indicated that care provided to cancer patients outside specialized institutions is often of lower quality, even in areas where the availability of a substantial body of scientific knowledge should have led to a general consensus about what constitutes appropriate care.[1–4] Caregivers' personal characteristics (age, education, training, experience, and skill), attitudes, and beliefs are increasingly seen as the preeminent cause when large variations in practice patterns exist.[5,6]

A mail survey carried out in 1987 to investigate physicians' opinions on breast cancer surgery in Italy showed, for example, that doctors working in hospitals with larger volumes and those favoring patient participation in treatment decisions were more likely to recommend less radical surgery.[6,7] Based on these findings, one would expect unnecessary radical surgical procedures to be more common in hospitals with low breast cancer patient volumes.

To investigate whether the relationship held true in actual practice, we analyzed data from a study on patterns of breast cancer care carried out in Italy in 1983 and 1984, using the performance of Halsted mastectomy as indicator of quality of care.[8]

Methods

Data Collection and Criteria for Assessment of Surgical Appropriateness

The methodology of data collection has been reported in detail elsewhere.[3] Briefly, information on 1262 breast cancer patients was prospectively collected in 62 general hospitals from 11 Italian regions over the period from March 1983 through April 1984. All patients consecutively admitted and diagnosed at participating centers were eligible for entry into the study. Halsted mastectomies were considered inappropriate when they were performed on patients without tumor fixation to the pectoral muscle and with nodal status classified as N_{0-1}.[9] We excluded from this analysis 277 patients for whom no specific recommendation was included in the guidelines because their tumors were adherent to the skin; they had clinical involvement of the supraclavicular axillary nodes; they had distant metastasis; they did not undergo surgery; or they lacked information on the clinical stage of disease.[9] Thus, the present report is based on data from 985 breast cancer patients.

Data Analysis

We first performed a series of univariate analyses to see whether the probability of being treated inappropriately with Halsted radical mastectomy was associated with patients' social and clinical characteristics, hospital size (number of beds), or volume of patients (based on the total number of patients enrolled in the study over the 1-year accrual period). The Mantel-Haenszel chi-square test and (when appropriate) the Mantel-Haenszel chi-square test for linear trend[10] were used to assess the statistical significance of the association. The strength of the associations was assessed by means of odds ratios (ORs) with 95% confidence intervals (CIs). Adjustment for potential confounding factors was done with the Mantel-Haenszel procedure.[10] Final analysis was performed through logistic regression[11]: the model included as independent variables all vari-

ables with an individually statistically significant ($P < .05$) association, identified with a stepwise procedure.

Results

The mean age of the patients whose cases were reviewed was 57 years (range 30–84). Overall, 366 patients (34%) were treated with Halsted radical mastectomy; 266 procedures (79%) were inappropriate. As shown in Table 1, more educated patients were 50% less likely to undergo Halsted mastectomy; the association held true even after adjusting for age and disease stage (OR = 0.53; 95% CI = 0.31, 0.89).

Halsted mastectomy was more frequent among patients with more advanced disease: 41% of clinical stage III patients, compared with 22% of stage I and 26% of stage II patients, had the procedure ($\chi^2 = 9.59$, $P = .001$) (Table 2). The same association held true both when pathologic stage was considered and when its two components (size of the primary tumor and nodal status) were considered separately (Table 2).

The use of inappropriate radical mastectomy was closely related to both volume of patients and hospital size. Centers with lower patient volume (1 through 10 and 11 through 20) had higher inappropriateness rates—43% and 36%, respectively, compared with 21% for hospitals seeing more than 20 patients per year (χ^2 for linear trend = 35.5, $P < .001$). A univariate analysis showed that patients seen at low-volume hospitals had double the probability of receiving a Halsted mastectomy (OR = 2.37; 95% CI = 1.78, 3.16). Hospital size also played a role: Halsted mastectomies were inappropriately performed on 36% of patients seen at smaller centers, compared with 24% cared for at larger hospitals (OR = 1.68; 95% CI = 1.21, 2.33).

Table 3 shows the proportion of patients treated with inappropriate Halsted mastectomy within the two categories of hospital size stratified by patient volume. Although the association between quality of surgery and patient volume had the same direction in the two strata, it was statistically significant only in the larger centers, where patients admitted to low-volume hospitals had double the probability of an unnecessary radical procedure (OR = 2.67; 95% CI = 1.88, 3.78).

A multivariate analysis showed that women seen at high-volume hospitals were less likely to be treated with an unnecessary radical mastectomy (OR = 0.36; 95% CI = 0.23, 0.55) (Table 4). Based on the logistic model including all the relevant covariates, probabilities of being treated with an inappropriate Halsted mastectomy were 48%, 43%, and 24% for hospitals recruiting 1 through 10, 11 through 20, and more than 20 patients per year, respectively.

Discussion

Approximately one third of the breast cancer patients in our study were treated with a surgical procedure that, by current standards, should be performed in only a minority of cases; it is thus not surprising that in almost 80% of the cases the procedure was judged to be inappropriate. It is hard to believe that hospital organization and availability of specific facilities account for these findings. If these factors play any role it should be only in the diffusion of conservative procedures, for

which postsurgical radiotherapy is mandatory.

The key finding of this study—the relationship between patient volume and quality of care—is not new and is consistent with the findings of several other studies. Moreover, it held true for other aspects of breast cancer care, such as timeliness of diagnosis and performance of radiotherapy after conservative surgery.[12–14] The latter fact is of specific importance because it offers an opportunity to identify medical communities at risk of providing poor quality care and to identify sites more in need of educational interventions.

Although one might argue that our findings are based on outdated practice patterns, an analysis based on information gathered in a more recent study, at the end of the 1980s, showed that the use of Halsted mastectomy was still high.[15] Moreover, even in the more recent study we found the same association between patient volume and use of unnecessary radical procedures. As Table 5 shows, data from both surveys are consistent with a 70% reduction in the risk of being treated with an inappropriate Halsted mastectomy in high-volume centers.

A few potential limitations of our study should be discussed. Our measure of volume was only a proxy for the actual number of patients seen in 1 year (see Methods). However, as the study was descriptive, it is hard to see why patients should have been selectively excluded depending upon the surgery they had had. Moreover, it is likely that the association we found would have been stronger had we used a more precise measure of the actual number of patients treated.

Some hospital self-selection may have occurred, given that participation was voluntary. A closer comparison of our hospital sample with the universe of Italian hospitals[16] indicated, however, that proportionally larger and better technically equipped hospitals entered this study, making our results even more worrying. Hospitals seeing more than 20 breast cancer patients per year in Italy account for approximately one sixth of the estimated 30 000 new cases of the disease diagnosed every year in the country.[16] Therefore, we estimate that about 2500 avoidable (inappropriate) Halsted procedures were carried out during the study period. □

Predictors of Nursing Home Admission in a Biracial Population

Marcel E. Salive, MD, MPH, Karen S. Collins, MD, MPH, Daniel J. Foley, MS, and Linda K. George, PhD

ABSTRACT

Racial differences in predictors of institutionalization were studied in a biracial North Carolina cohort (n = 4074). During 3 years of follow-up, 8.5% of Whites and 6.4% of African Americans were admitted to nursing homes. African Americans were one half as likely as Whites to be institutionalized after adjustment for other risk factors. Among Whites, impaired activities of daily living and cognition were the strongest predictors; among African Americans, impaired instrumental activities of daily living and prior history of nursing home use were strongest. Racial differences in nursing home use were not explained by financial and social support or physical and cognitive impairment. (*Am J Public Health.* 1993;83:1765–1767)

Introduction

Older adults seek nursing home care primarily because of physical or mental impairment secondary to illness in advanced age and the lack of informal care.[1–3] Racial disparities have been reported such that 27% of African Americans can expect to use nursing homes in their lifetime, as compared with 38% of Whites.[4]

This analysis was designed to (1) compare nursing home use by African Americans and Whites while controlling for social support, economic status, and physical and cognitive function and (2) assess the relative importance of selected predictors of institutionalization within each racial group.

Methods

Study Population

The data were derived from the five-county North Carolina community of the Established Populations for Epidemiologic Studies of the Elderly, a collaborative longitudinal study of men and women 65 years of age or older. Details of the methods have been published.[5,6] During 1986 and 1987, trained interviewers conducted household surveys to collect baseline information from 4163 people (80% of eligible respondents). This study includes 4074 community-dwelling persons, classified by the interviewer as Black (55%) or White, who were followed for up to 3 years. Other races and persons without adequate follow-up to assess subsequent institutionalization were excluded.

Annual interviews ascertained interval admission to intermediate or skilled nursing facilities and personal care homes. Follow-up rates were greater than 95% each year among those initially interviewed. If a participant died, institutionalization since the last interview was ascertained from a proxy.

During the initial interview, information on age, gender, education, household income, marital status, household composition, types of medical insurance, urban or rural residence, and prior use of health services (home health aide, visiting nurse, or nursing home) was obtained. Social support was measured as perceived availability of support and instrumental support.[7] Physical function was measured as limitations in activities of daily living[8,9] and in instrumental activities of daily living.[10] Cognitive impairment was defined as four or more errors on the modified Short Portable Mental Status Questionnaire.[11,12]

Statistical Analysis

The baseline population was used to directly adjust the incidence of nursing home admission by age.[13] Logistic regression models used nursing home admission as the dependent variable in multivariate analyses examining the hypothesis that racial differences could be explained by demographic characteristics and social and functional status.[14,15] Logistic regression models stratified by race were examined to evaluate whether the factors associated with institutionalization differed by race. Sampling weights were used in all analyses to represent population estimates for the five counties.

Results

During the follow-up, 311 (7.6%) persons reported at least one nursing home admission. Blacks were institutionalized 24% less than Whites (3-year age-adjusted incidence rates of 6.4% and 8.5%, respectively; Table 1). Among those 85 years of age or older, Black women had the lowest rates.

1–2 ADL impairments	7.2	1.7	0.9, 3.3	7.7	1.2	0.7, 2.2
≥3 ADL impairments	3.1	5.1	2.0, 13.0	4.4	1.7	0.8, 3.4
Instrumental ADL (per impairment)	26.7	1.0	0.9, 1.2	36.6	1.3	1.2, 1.5
Cognitive impairment	6.3	4.7	2.2, 10.0	19.1	1.2	0.7, 2.0
Prior nursing home use	2.7	1.8	0.7, 4.6	1.4	5.2	1.7, 16.0

Note. ADL = activities of daily living; CI = confidence interval. Relative odds were computed from race-specific multivariate logistic regression models based on nursing home admissions of 171 White participants ($r = .48$, predictive accuracy coefficient = .85) and 140 Black participants ($r = .42$, predictive accuracy coefficient = .79). Models were adjusted for age, sex, and all main effects shown.

Based on a model for the entire cohort, the following characteristics were significantly ($P < .05$) associated with nursing home use: age, White race, impairment in activities of daily living, cognitive impairment, Medicaid eligibility, urban residence, prior nursing home use, living alone, unmarried, low perceived availability of support, and having fewer children. Blacks were only half as likely as Whites to be institutionalized (relative odds = 0.50, 95% CI = 0.35, 0.72) after these variables were controlled.

Among elderly Whites, urban residence, living alone, low perceived social support, impairment in activities of daily living, cognitive impairment, and having fewer children were significantly ($P < .05$) associated with nursing home use (Table 2). Among Whites, limitations in three or more activities of daily living and cognitive impairment increased the risk of institutionalization approximately fivefold. Among African Americans, nursing home admission was significantly associated with fewer predictors, specifically prior nursing home use, impairment in instrumental activities of daily living, and perceived social support.

Discussion

This longitudinal analysis of nursing home use in a biracial North Carolina community serves to clarify and challenge some long-standing beliefs about explanations for racial differences in institutionalization. In 3 years of follow-up, African Americans were admitted to nursing homes about half as often as Whites after adjustment for several confounding factors. Although this population is geographically based, these differences have been reported nationally,[1] and the explanation may, in part, cut across regional lines.[16]

Our results highlight specific differences in predictors of institutionalization between these two racial groups. Among Whites, urban residents were more likely to be institutionalized than were their rural neighbors. Furthermore, physical and cognitive impairment were leading risk factors for admission of Whites but not African Americans. This may reflect differing cultural attitudes toward disability, a need to have the person at home regardless of impairment,[17,18] or limited knowledge of the long-term care system. Moreover, the Short Portable Mental Status Questionnaire may have divergent ability to accurately screen for impairment across racial groups. Although research in this area is limited, lifetime experiences such as segregated schools and job discrimination may contribute to poor performance on mental status questionnaires, leading to unreliability of such screening tests across cultures or ethnic groups.[19] Evaluation of more sensitive and specific screening instruments in the appropriate population is needed to address this issue. In African Americans, instrumental activities of daily living and prior nursing home

use may also reflect underlying physical and cognitive impairment.

We found significant unexplained differences in institutionalization rates between African Americans and Whites in this population. Therefore, either we were not able to capture one or more additional factors that influence this difference at the individual or community level or the measures that we used as confounders were incomplete. The baseline data collection was extensive but did not include personal or caregiver attitudes toward institutionalization. Also, we did not measure precisely the use of home care as an alternative for institutionalization.

These results suggest that, in addition to physical and cognitive changes that occur with aging, underlying social and historical differences may, at some level, influence current patterns of nursing home use. This analysis cannot address whether African Americans at home are better or worse off than their White counterparts. Our results do question, however, the way in which racial differences have been explained in the past without complete information. Future work should examine the current and future needs of African Americans and other minorities for access to long-term care services. □

The Behavioral Risk Factor Surveillance System Questionnaire: Its Reliability in a Statewide Sample

Aryeh D. Stein, PhD, Ruth I. Lederman, MPH, and Steven Shea, MD

ABSTRACT

The reliability of the Behavioral Risk Factor Surveillance System questionnaire was assessed in a random sample of adults (n = 122) and a separate sample of Black and Hispanic adults (n = 200) in Massachusetts. The questionnaire was administered twice, 21 to 44 days apart, by telephone (210 completed reinterviews, 65% response rate for second administration). There were no statistically significant differences in the distribution of demographic or risk factor variables across administrations. Individual-level reliability (kappa for categorical variables, correlation for continuous variables) for demographic characteristics was more than 0.80 for White respondents and more than 0.60 for Black and Hispanic respondents. Employment and income were reported less consistently than other variables. Reliability coefficients for behavioral risk factors were generally above 0.70. Exceptions were variables with extreme distributions. These data support the use of the Behavioral Risk Factor Surveillance System questionnaire for surveillance and research. (*Am J Public Health.* 1993;83: 1768–1772)

Introduction

The Behavioral Risk Factor Surveillance System (BRFSS), an ongoing surveillance program developed and funded by the Centers for Disease Control and Prevention (CDC), is designed to estimate the prevalence of risk factors for the major causes of death in the United States.[1] Data from the BRFSS are a central component of federal and state activities designed to monitor progress toward achieving the health objectives for the year 2000.[2] We assessed the test–retest reliability of the BRFSS questionnaire in a representative sample of Massachusetts residents.

Methods

The BRFSS questionnaire has been described in detail elsewhere.[1] Demographic and risk factor variables are shown in Tables 1 and 2.

Two separate populations were recruited. The first consisted of respondents to the regular March 1992 sample of the Massachusetts BRFSS. The sampling methods were consistent with published CDC procedures. All interviews were conducted in English. Inability of the selected individual to participate in a telephone interview or speak English was considered a cause of ineligibility. With known eligible households as the denominator, the response rate for this survey was 65%.

The second population consisted of a separately recruited sample of Black and Hispanic residents of Massachusetts. The sampling frame for this study consisted of telephone exchanges in towns identified in the 1990 census as containing high concentrations of Blacks and Hispanics. Households were eligible if at least one household member was identified by the initial respondent as being Black or Hispanic. A random member of the household, irrespective of ethnicity, was interviewed. If necessary, a translation prepared by the CDC was used to conduct the interview in Spanish. With known eligible households as the denominator, the response rate for this survey was 39%.

A computer-assisted telephone interview system was used to collect data. In the first interview, respondents were not told that they might be contacted again. Callbacks for the second interview began 21 days after the first interview. Efforts were made to reinterview all of the original respondents, and these efforts were of the same intensity as those used to obtain the first interview. Eighty-six of 122 respondents to the regular survey (70%) and 124 of 200 respondents to the minority survey (62%) were successfully reinterviewed. Ninety-five percent of the 210 successful second interviews were completed within 44 days, and all were completed within 64 days. Univariate distributions of demographic variables, as recorded during the first interview, did not differ significantly ($P > .05$ for each demographic variable) between the 210 respondents and the 112 nonrespondents to the repeat interview.

Subjects were asked to identify race and whether they were of Hispanic origin. Subjects were classified as White non-Hispanic, Black non-Hispanic, or Hispanic according to the categories used by the CDC in reporting BRFSS data. Of 86 participants in the first sample, 11 were classified as non-White based on their responses to the first interview. Of 124 participants in the second sample, 15 were classified at the first interview as neither Black non-Hispanic nor Hispanic. Data from these 26 individuals were included in pooled analyses but were excluded from race/ethnicity-specific analyses.

At the time of the study, Aryeh D. Stein and Ruth I. Lederman were with the Bureau of Health Statistics, Research and Evaluation, Massachusetts Department of Public Health, Boston. Aryeh D. Stein was also with the Division of Epidemiology, Columbia University School of Public Health, New York, NY. Steven Shea was with the Division of Epidemiology, Columbia University School of Public Health, and the Division of Medicine, College of Physicians and Surgeons, Columbia University.

This paper was accepted May 11, 1993.

Algorithms developed at the CDC (Dr Emma Frazier, written communication, July 1992) were used in computations of behavioral risk status from questionnaire items. Individuals with unknown values for demographic characteristics on either administration of the questionnaire were excluded from determination of group distributions for that administration. An exception was income; more than 5% of respondents refused to state or reported not knowing their annual household income and were considered a stratum for analysis. Individuals of unknown risk factor status were considered not to be at risk. This approach consistently underestimates prevalence because unknown responses are retained in the denominator.

The *z* test (for dichotomous variables and proportions, such as gender and risk status), the chi-square test (for polychotomous variables, such as educational attainment), and the *t* test (for means of continuous variables, such as cholesterol level) were used in assessing the consistency of distributions. The kappa statistic[3] (for dichotomous variables), unweighted kappa (for polychotomous variables), and Pearson's correlation coefficient (for continuous variables) were used in examining the consistency of individual responses. Individuals with unknown values on ei-

TABLE 1—Demographic Characteristics Available for Analysis in the 1992 Behavioral Risk Factor Surveillance System Questionnaire

Demographic Characteristic	Categories Used in Analysis
Age	Recorded in exact y
Sex	Male Female
Education	No high school/some high school High school graduate/some technical school/technical school graduate Some college but did not graduate College graduate/postgraduate or professional degree
Marital status	Married/living as a couple Divorced/separated Widowed Never married
Employment	Employed Self-employed Unemployed less than 1 y/unemployed more than 1 y Homemaker Retired Student
Income	Under $10 000/$10 000–$15 000 $15 000–$20 000/$20 000–$25 000/$25 000–$35 000 $35 000–$50 000/over $50 000 Unknown/refused
Race/ethnicity[a]	White but not of Hispanic origin Black but not of Hispanic origin Hispanic of any race Asian, Pacific Islander, or Native American/other/unknown/refused

Note. Categories separated by a slash were differentiated during the interview but combined for this report.
[a]Categories were defined on the basis of responses to the questions "What is your race?" and "Are you of Hispanic origin?"

TABLE 2—Risk Behaviors and Characteristics Available for Analysis in the Core Modules of the 1992 Behavioral Risk Factor Surveillance System Questionnaire

Module	Risk Behavior/Characteristic	Definition
Safety belts	Safety belt nonuse	Does not always use safety belt when driving or riding in a car
Hypertension	Recent blood pressure check	Has had blood pressure measured in past 2 y
	Diagnosed hypertensive	Has been told on more than one occasion that blood pressure was high or is taking blood pressure medication
Cholesterol	Recent cholesterol check	Has had cholesterol checked in past 5 y
	Cholesterol awareness	Can state own cholesterol level as a number
	Serum cholesterol	Cholesterol level stated as a number
	Hypercholesterolemia	Cholesterol level 200 mg/dL or higher
Exercise	Sedentary life-style	Did not exercise in past mo
	Regular aerobic exercise	Performed an aerobic activity at least three times per wk for at least 20 min per occasion in past mo
Smoking	Current cigarette use	Smoked 100 or more cigarettes over lifetime and currently smokes
	Cigarette consumption	Number of cigarettes smoked daily
	Former cigarette use	Smoked 100 or more cigarettes over lifetime but does not currently smoke
Alcohol	Any consumption	Any alcoholic drinks consumed in past mo
	Total consumption	Number of alcoholic drinks consumed in past mo
	Chronic consumption	Drank 60 or more alcoholic drinks in past mo
	Acute consumption	Drank five or more alcoholic drinks on an occasion at least once in past mo
	Drives after alcohol consumption	Drove a car after consuming too much alcohol at least once in past mo
Obesity	Body mass index	Weight in kilograms divided by square of height in meters
	Obese	Body mass index exceeding 27.8 kg/m^2 (men) or 27.3 kg/m^2 (women)
	Weight control	Currently trying to lose weight
Diabetes	Diagnosed diabetes	Doctor-diagnosed diabetes

TABLE 3—Consistency of Distribution of Demographic Characteristics across Two Administrations of the Behavioral Risk Factor Surveillance System Questionnaire among 210 Respondents: Massachusetts, 1992

Demographic Characteristic	All Respondents (n = 210)		White Non-Hispanic (n = 76)		Black Non-Hispanic (n = 64)		Hispanic (n = 45)

>$35 000	29.5	30.5	45.3	48.0	23.4	25.0	17.8	17.8
Unknown/refused	6.7	5.7	4.0	2.7	10.9	6.3	6.7	11.1
Race/ethnicity, %								
White	39.1	37.6	...	...	...	...	...	...
Black	31.4	32.4	...	...	...	...	...	...
Hispanic	24.3	24.8	...	...	...	...	...	...
Other	5.2	5.2	...	...	...	...	...	...

Note. The total for all respondents is greater than the sum of White non-Hispanic, Black non-Hispanic, and Hispanic respondents as a result of exclusion of 28 subjects from ethnicity-specific analyses (see text for details). None of the differences between time 1 and time 2 values were significant ($P > .05$) within the whole sample or each ethnicity separately. The consistency of distribution of race/ethnicity was not compared for ethnicity-specific strata; it should be noted that the distribution of race/ethnicity in this sample does not reflect the ethnic composition of Massachusetts because of oversampling of Black and Hispanic residents.

ther administration of the interview for demographic characteristics or continuous variables and those for whom the continuous variable was not asked (e.g., number of cigarettes smoked among nonsmokers) were excluded from tests of individual consistency.

Results

Differences across administrations for demographic characteristics and risk factors were generally small (Tables 3 and 4). At the individual level, employment and income were reported less consistently than the other demographic variables (Table 5). Black and Hispanic respondents tended to report educational attainment, employment status, and income less consistently than did White respondents. Reliability was generally high for behavioral risk factors (Table 6), with most coefficients above .70 and many above .80. Consistency tended to be lower among Hispanic respondents than among White or Black respondents, although the differences were not marked.

Discussion

This paper suggests good test–retest reliability of the BRFSS questionnaire. Our data are consistent with the results of an earlier, more restricted study,[4] and extend these results to an analysis of the complete core BRFSS questionnaire in a statewide sample. Two studies have shown fair to good consistency of group mean prevalence of selected risk factors,[5,6] but no published studies have addressed the validity of individual responses. Our study should be relevant to all agencies participating in the BRFSS, because we adhered to BRFSS subject recruitment and data collection protocols. Our results concerning individual-level reliability are of potential interest to epidemiologic studies involving telephone-based surveys.[7]

True change between administrations of the questionnaire leads to lower estimates of reliability. Conversely, if the time period between administrations is too short, the questionnaires cease to be independent. In the present study, the time interval between the two administrations was 21 to 44 days. For most behaviors and characteristics, this interval was probably adequate. Questions concerning alcohol consumption and exercise, which addressed behaviors occurring in the previous month, showed the lowest consistency. For these variables, under the conditions of our study, it is not possible to separate questionnaire effects from true change. The sample size was too small to

Obesity	Body mass index, no. reporting	200	204	74	73	61	63	40	42
	Body mass index, mean (SD)	25.9 (4.8)	26.2 (4.9)	25.6 (4.0)	25.6 (3.8)	27.9 (6.1)	27.9 (6.0)	24.7 (3.7)	26.2 (4.6)
	Obese, %	27.6	30.5	26.7	24.0	42.2	40.6	20.0	33.3
	Trying to lose weight, %	47.6	39.5	48.0	42.7	51.6	40.6	44.4	37.8
Diabetes	Diagnosed diabetes, %	6.2	5.2	5.3	4.0	10.9	10.9	4.4	2.2

Note. The total for all respondents is greater than the sum of White non-Hispanic, Black non-Hispanic, and Hispanic respondents as a result of exclusion of 26 subjects from ethnicity-specific analyses (see text for details). None of the differences between time 1 and time 2 values were significant ($P > .05$) within the whole sample or each ethnicity separately.

assess the effect on estimates of reliability of varying intervals between the two administrations.

Participation in the first interview may have prompted some respondents to modify their life-style, but this did not appear to be the case, inasmuch as there was no overall improvement in the health profile of the sample. A related issue is that if the population is homogenous with respect to the characteristic being studied, estimates of reliability become highly sensitive to small departures from perfect concordance.[8] This may explain the lower estimates of reliability for recent blood pressure check (prevalence at first administration of 96.7%), chronic alcohol consumption (prevalence of 2.9%), and driving after alcohol consumption (prevalence of 1.9%). For the race/ethnicity-specific analyses, instability due to extreme mar-

TABLE 5—Consistency of Individual Responses to Two Administrations of the Demographics Module of the Behavioral Risk Factor Surveillance System Questionnaire among 210 Respondents: Massachusetts, 1992

Demographic Characteristic	Reliability			
	All Respondents (n = 210)	White Non-Hispanic (n = 75)	Black Non-Hispanic (n = 64)	Hispanic (n = 45)
Age	1.00	1.00	1.00	.97
Sex	1.00	1.00	1.00	1.00
Education	0.80	0.89	0.76	0.62
Marital status	0.93	0.95	0.98	0.86
Employment	0.77	0.93	0.71	0.63
Income	0.75	0.82	0.65	0.67
Race/ethnicity	0.87	...	...	...

Note. Age was retained as a continuous variable. Pearson's correlation coefficient was used to estimate reliability of age. Kappa was used to estimate reliability of categorical variables. In instances in which a demographic characteristic included more than two categories, unweighted kappa was computed. See Table 1 for the number of categories used in computing kappa. All reliability coefficients were highly significant ($P < .001$). All analyses were based on the complete sample, except for age among all respondents (n = 208) and White respondents (n = 74) and education among all respondents (n = 206), Black respondents (n = 63), and Hispanic respondents (n = 43). Kappa was not computed for consistency of race/ethnicity classification within ethnicity-specific subgroups.

TABLE 6—Consistency of Individual Responses to Two Administrations of the Behavioral Risk Modules of the Behavioral Risk Factor Surveillance System Questionnaire among 210 Respondents: Massachusetts, 1992

Module	Risk Behavior/ Characteristic	Reliability			
		All Respondents (n = 210)	White Non-Hispanic (n = 75)	Black Non-Hispanic (n = 64)	Hispanic (n = 45)
Safety belt	Safety belt nonuse	0.76	0.81	0.77	0.75
Hypertension	Recent blood pressure check	0.81	0.85	−0.03	0.79
	Diagnosed hypertension	0.89	1.00	0.87	0.83
Cholesterol	Recent cholesterol check	0.77	0.83	0.83	0.57
	Hypercholesterolemia	0.86	0.88	0.86	0.73
	Cholesterol awareness	0.80	0.83	0.64	0.60
	Actual cholesterol level	0.88 (n = 42)	0.85 (n = 25)	1.00 (n = 3)	0.96 (n = 5)
Exercise	Sedentary life-style	0.57	0.59	0.50	0.63
	Regular aerobic exercise	0.45	0.61	−0.07	0.64
Smoking	Current smoker	0.83	0.90	0.79	0.85
	Number of cigarettes per d	0.73 (n = 49)	0.60 (n = 18)	0.83 (n = 13)	0.70 (n = 10)
	Former smoker	0.73	0.86	0.67	0.58
Alcohol	Any alcohol consumption	0.82	0.93	0.73	0.73
	Number of drinks per mo	0.72 (n = 103)	0.79 (n = 54)	0.57 (n = 20)	0.60 (n = 17)
	Chronic consumption	0.53	0.55	...[a]	...[a]
	Binge consumption	0.64	0.67	0.57	0.55
	Drink and drive	−0.01	...[a]	...[a]	...[a]
Obesity	Body mass index	0.90 (n = 198)	0.97 (n = 73)	0.91 (n = 61)	0.59 (n = 39)
	Obese	0.77	0.86	0.84	0.55
	Weight control	0.72	0.73	0.72	0.68
Diabetes	Diagnosed diabetes	0.82	0.85	1.00	−0.03

Note. Kappa was used to estimate reliability for dichotomous variables. Pearson's correlation coefficient was used to estimate reliability for continuous variables (actual cholesterol level, number of cigarettes per day, number of drinks per month, body mass index). Analyses were performed on data from all respondents except where specified. For continuous variables, reliability was computed only for respondents with nonzero, nonmissing values at both administrations. All kappa coefficients were highly significant ($P < .001$), except for recent blood pressure check and regular aerobic exercise among Black respondents, driving after alcohol consumption in the whole sample, and diagnosed diabetes among Hispanic respondents ($P > .05$ for each). It should be noted that the low values of kappa reflect extreme marginal prevalence of the risk behaviors rather than a large proportion of discordant cells. All correlation coefficients were significant ($P < .001$), except cholesterol level among Black ($P = .014$) and Hispanic ($P < .01$) respondents, number of cigarettes among White ($P < .01$) and Hispanic ($P = .024$) respondents, and number of drinks per month among Black ($P < .01$) and Hispanic ($P < .01$) respondents.

[a]Prevalence of zero at either time 1 or time 2, kappa not computed.

ginal prevalence was compounded by the smaller sample sizes, leading in some instances to uninterpretable negative values for the kappa statistic.

A limitation of this study is the low response rate to the initial interviews. The response rate for the main sample was consistent with that obtained in Massachusetts over the previous 3 years,[9] although it was lower than that of most other states participating in the BRFSS (C. Leutzinger, written communication, June 1992). For the minority study, the response rate to the initial interview was 39%; therefore, estimates of prevalence derived from this study may be subject to sampling bias. The response rate for the second interview was higher: 62% for the minority sample and 70% for the main sample. Thus, we are able to state with fair confidence that, among responders, consistent responses may be obtained for most parameters. We cannot assess whether reliability differs between responders and nonresponders.

In conclusion, the BRFSS questionnaire yields highly consistent group mean estimates of prevalence when administered repeatedly to the same individuals. Individual reliability is also high. This study, together with previous studies of reliability and validity,[4–6] supports the use of the BRFSS questionnaire in surveillance activities. □

Acknowledgments

This study was funded through a cooperative agreement between the Centers for Disease Control and Prevention, the Massachusetts Department of Health, and the Massachusetts Health Research Institute.

American Journal of Public Health

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Adiposity and Stroke among Older Adults of Low Socioeconomic Status: The Chicago Stroke Study

Loretta DiPietro, PhD, MPH, Adrian M. Ostfeld, MD, and Gary L. Rosner, ScD

ABSTRACT

Objectives. **The purpose of this study was to test the hypothesis that overall and truncal adiposity increase the risk of stroke independent of their association with cardiovascular disease risk factors and other preexisting illnesses.**

Methods. **Analyses were conducted of longitudinal data from a poor, biracial cohort of noninstitutionalized adults 65 to 74 years of age who participated in the Chicago Stroke Study from 1965 to 1970.**

Results. **Ponderal index (cm/kg$^{1/3}$) and chest skinfold were significantly associated with systolic and diastolic blood pressure, serum cholesterol and triglycerides, plasma glucose, and smoking. Ponderal index was also associated with diabetes and risk of stroke. After potential confounders were controlled, the following variables showed significant independent associations with risk of stroke: Black race, female gender, and age 70+; hypertensive heart disease; and diabetes. Neither adiposity variable was associated with risk of stroke in the presence of these powerful predictors.**

Conclusions. **Control of hypertension and diabetes continues to be important among older adults. Since excess adiposity seems to influence risk of stroke through its association with these disorders and other cardiovascular disease risk factors, control of weight and fat remains an important concern as well. (*Am J Public Health.* 1994;84:14–19)**

Introduction

Epidemiologic studies of the relationship between overall obesity and cardiovascular disease have yielded inconclusive results.[1–6] Recent studies that have focused specifically on fat distribution, however, have demonstrated an increased risk of cardiovascular disease or mortality with increasing levels of abdominal adiposity.[7–11]

Adiposity gained in later adulthood tends to accumulate on the trunk and upper body rather than the periphery,[12] particularly among postmenopausal women.[12] An android type of fat patterning, characterized by an excess of upper-body fat relative to lower-body fat[13] and composed of hypertrophied fat cells, is both diabetogenic and atherogenic.[13–20] Since diabetes, hypertension, and altered plasma lipid profiles are primary risk factors for cardiovascular disease, excess truncal fat may serve as a more basic risk factor in its etiology. Whether overall adiposity or truncal adiposity exerts an independent effect on risk of cardiovascular disease remains unclear.

Most of the studies on adiposity and cardiovascular disease have been limited to middle-aged populations at highest risk of coronary heart disease. Much less is known about how adiposity influences the risk of cerebrovascular disease among older adult populations. This is especially true for older Black women, among whom the prevalence of obesity, as well as hypertension and diabetes, tends to be disproportionally high relative to older men and women of other races.[21,22]

In order to examine the multivariable association between a measure of overall adiposity (the ponderal index), a measure of truncal adiposity (the chest skinfold), and the risk of stroke among a poor, biracial, older adult population, we analyzed data from a cohort of individuals who participated in the Chicago Stroke Study.[23] Earlier work by Ostfeld et al.[24] demonstrated a simple relationship between the ponderal index and stroke in this Chicago cohort. The primary hypothesis tested in the current analysis was that both overall adiposity and truncal adiposity increase the risk of stroke among older adults, independent of their association with cardiovascular disease risk factors and preexisting illness other than cardiovascular disease.

Methods

The Chicago Stroke Study was conducted from 1965 to 1970 with three probability samples of noninstitutionalized adults who were 65 to 74 years of age, lived in Cook County, Illinois, and were receiving old age assistance (public assistance to those with virtually no income and with possessions worth less than $400). Eligible subjects were classified into four strata by race (White/Black) and sex. Sampling fractions were used to secure equal numbers of each race–sex stratum. The sampling methods have been described in detail elsewhere.[23]

Loretta DiPietro and Adrian M. Ostfeld are with the School of Medicine, Department of Epidemiology and Public Health, Yale University, New Haven, Conn. At the time this article was written, Gary L. Rosner was also with the School of Medicine, Department of Epidemiology and Public Health, Yale University. He is now with the Duke University Medical Center, Department of Cancer and Biostatistics, Durham, NC.

This paper was accepted May 11, 1993.

Of the 4759 individuals in the original target population, 9% could not be located, 19% refused to participate, and 6% died in the interval between the time of sampling and the initial medical examination. Therefore, 3141 (66%) subjects underwent the initial examination. Baseline examinations were conducted between September 1965 and February 1967. Since the primary purpose of the study was to determine the factors affecting the risk of stroke, those individuals with a prior history of cerebrovascular injury (n = 368) were excluded from the analysis. Therefore, the study population comprised 2773 persons.

The period of follow-up was between September 1965 and March 1970; the median follow-up period for the study cohort was 32.1 months. During the follow-up period, 21% of the subjects died, 3% moved from the Chicago area, and 0.7% could not be traced.

The initial history and medical examinations were virtually identical to those of the Framingham study, except for inclusion of items germane to examination of the nervous system and determination of the risk factors for stroke. Additional diagnostic procedures included a 12-lead electrocardiogram, retinoscopy, blood lipid levels, serum glucose levels obtained 1 hour after oral intake of 50 g of glucose, systolic and diastolic blood pressure, forced expiratory volume for 1 second, height, weight, and chest skinfold thickness measured over the lateral surface of the 10th rib.[24]

Categories of preexisting clinical cardiovascular disease upon initial examination included myocardial infarction, angina pectoris, congestive heart failure, peripheral arterial disease, hypertensive heart disease, and stroke. Subjects were divided into these diagnostic categories based on criteria previously outlined by Ostfeld et al.[24] All persons with clinical heart disease, transient ischemic attacks, peripheral atherosclerosis, intermittent claudication, definite electrocardiogram abnormalities, history of diabetes mellitus, blood urea nitrogen of 30 mg/dl or more, or health status rated as gravely ill at baseline were classified as Population A. Population B consisted of subjects without any of these conditions. This stratification was done to determine whether the various risk factors for stroke operated independently of cardiovascular or closely related diseases.

Definition of Stroke

Individuals free of a prior stroke upon the initial medical examination were followed until a stroke or death occurred or until March 1970, when the follow-up period ended. In order to identify those subjects who developed new cerebrovascular injuries, all subjects were visited biannually by field workers trained to observe signs of strokes and transient ischemic attacks. A trained research supervisor evaluated these data against strict criteria for selecting individuals for follow-up examination by a board-certified neurologist (88% of the subjects who experienced signs and symptoms of stroke and who survived were examined by the neurologist). As long as the information was negative for the possibility of a stroke, the subject was reevaluated at the next biannual exam. The Cook County Hospital provided another source of morbidity and mortality data, since approximately 88% of hospitalizations among the study population occurred there. Admissions to this hospital were screened daily to determine whether subjects were hospitalized, the diagnosis, and, if relevant, the cause of death. The same morbidity and mortality data were collected from other hospitals in which cohort members were admitted, but this information was obtained at wider intervals.

All diagnostic decisions were made by a neurologist according to criteria established at the onset of the study. For living subjects, decisions were based on examinations performed by a neurologist or senior resident. Diagnostic decisions for deceased individuals were based on medical and hospital records, death certificates, or autopsy reports. Differentiations between brain infarct and hemorrhage were made whenever sufficient data were available.

Adiposity

Overall baseline adiposity was assessed by the ponderal index ($cm/kg^{1/3}$) in order to remain consistent with previously published reports from these data.[24] The ponderal index is inversely associated with adiposity and correlated almost perfectly with both body mass index (kg/m^2) ($r = -.96$) and relative weight (percentage of ideal weight) ($r = -.96$) among our study population. For a man of average height, a ponderal index of 41.8 $cm/kg^{1/3}$ corresponds to a body mass index of 23.8 (percentage of ideal weight = 100); a ponderal index of 39.6 $cm/kg^{1/3}$ corresponds to a body mass index of 27.8 (percentage of ideal weight = 120), which is a cutpoint often used to define obesity.[25] Truncal adiposity was assessed at baseline by a chest skinfold measured over the lateral surface of the 10th rib with Best calipers[26] and recorded in millimeters. Accurate skinfolds could not be measured for 200 subjects (7%) because the fat layer surrounding the 10th rib was larger than what the calipers could measure. Accordingly, the skinfolds of these subjects were recorded as 88 mm (the highest reading on the calipers), and the chest skinfold was categorized on the basis of quartiles of its distribution (<7 mm, 7 through 11.9 mm, 12 through 18.9 mm, or ≥19 mm).

Analysis

Univariate statistics were first generated on all study variables. A stroke was the outcome of interest and was first considered as a dichotomous variable. Pearson product–moment correlations, analysis of variance, the maximum likelihood ratio chi-square, and logistic regression[27] tested the simple associations among risk factors and between risk factors and the outcome.

We next considered time until the event of a stroke, measured in years from the start of the study, as the outcome variable. Cox proportional hazards modeling[28] was used to test the associations between the study variables of interest and rate of stroke while simultaneously controlling for important covariates and possible confounders, including preexisting disease states (Appendix). Two separate models were considered in the multivariable analysis, one containing the ponderal index measure and the other containing the chest skinfold measure.

In order to account for the sampling strata and to assess race-, sex-, and age-specific differences in risk of stroke, the dichotomous variables race, sex, and age (<70/≥70) were combined to form an eight-level interaction variable. This race–sex–age variable was included in all simple and multivariable analyses as a categorical indicator variable. A variable defining high blood pressure (yes/no) was used in place of both systolic and diastolic blood pressure in the multivariable Cox modeling procedures to test their threshold effect in predicting stroke. High blood pressure was scored 0 if systolic blood pressure was less than 160 mm Hg and diastolic blood pressure was less than 95 mm Hg, and it was scored 1 if otherwise; these cutpoints conform to the standard definition of high blood pressure at the time these data were collected. Since less than 10% of our population was on antihypertensive medication (and, among the users, adherence was generally low), use

TABLE 1—Mean Ponderal Index and Body Mass Index and Percentage Distribution of Chest Skinfold Quartiles by Race, Sex, and Age: Chicago Stroke Study

FEV, % FVC	−.32	.0001	.05	.0001

Note. FEV = forced expiratory volume for 1 second expressed as a percentage of forced vital capacity (FVC).
[a]Pearson product–moment correlation coefficient.
[b]Square of the coefficient of correlation based on analysis of variance.
[c]n = 2433.

of such medication was not considered in the definition of high blood pressure.

Odds ratios (ORs) based on the logistic regression estimates and rate ratios based on the Cox regression estimates, along with 95% confidence intervals (CIs), described the magnitude of effect for each level of the covariates compared with the reference category. All statistical procedures used the SAS (SAS Institute, Cary, NC) and BMDP (University of California, Berkeley) computer packages.

Results

Demographic and risk factor characteristics of the study population have been published previously by Ostfeld et al.[23]

Stroke

One hundred ninety-nine strokes occurred during the follow-up period. For 136 (68%) of these strokes, there was a clear history with confirming signs (designated as class I infarcts); 7 (3%) had a clear history without signs, 16 (8%) had a vague history with signs, 11 (6%) showed signs only, and 29 (15%) were determined from a death certificate. In order to be as inclusive as possible, all 199 strokes were included in the analysis. Most of these 199 strokes (80%) were nonembolic infarcts; 11% were hemorrhages, 2% were emboli, and 7% were undetermined.

Adiposity

In general, women had the lowest mean ponderal index (highest level of overall adiposity) in the study population (Table 1), and Black women had the highest prevalence of ponderal indices less than 38.1 (the lowest quartile). Differences in ponderal index between White and Black women were not statistically significant in either age category. Under age 70, women had a significantly lower ponderal index than did men of both races. After age 70, however, only White women showed significant differences in ponderal index from their male counterparts. Ponderal index did not change substantially with age. Also, women had more fat surrounding the chest wall than did men (Table 1). Black women had the highest proportion of skinfold measures greater than 19 mm, which represents the highest quartile of the distribution.

Adiposity and Other Risk Factors for Stroke

Both ponderal index and chest skinfold were significantly associated with systolic blood pressure, diastolic blood pressure, serum cholesterol, serum triglycerides, and plasma glucose (Table 2), although these correlations were of a rather modest magnitude. Ponderal index ($P < .0001$) and chest skinfold ($P < .0001$) showed significant inverse associations with current smoking in the presence of race, sex, and age. Ponderal index was also significantly associated with a history of diabetes while the race–sex–age variable was controlled for (OR = 0.95, 95% CI = 0.93, 0.98), whereas chest skinfold was not.

Risk Factors for Stroke

Overall, we found that the risk of stroke varied substantially by race, sex, and age in the simple analysis. Among subjects less than 70 years of age, Black men and women had more than twice the risk of stroke than White men (the referent category); among those 70 years of age or older, Black women had the highest risk of stroke (more than 3.5 times that of younger White men) (Table 3). Also, among subjects 70 years of age or older, the risk of stroke was twice as high for White subjects of both sexes as for their younger counterparts.

The following variables were significantly associated with the risk of stroke in the presence of the race–sex–age stratification variable alone: population code (B/A) (OR = 0.49, 95% CI = 0.35, 0.68), diabetes (OR = 1.81, 95% CI = 1.31, 2.53), hypertensive heart disease (OR = 2.52, 95% CI = 1.85, 3.41), left ventricular hypertrophy (OR = 1.41, 95% CI = 1.01, 1.99), hypertensive retinopathy (grade 1:

OR = 1.97, 95% CI = 1.33, 2.90; grades 2 through 4: OR = 2.51, 95% CI = 1.74, 3.65), and blood urea nitrogen (OR = 1.02, 95% CI = 1.01, 1.04). Ponderal index was also related to the risk of stroke, although the association was of marginal statistical significance (OR = 0.95, 95% CI = 0.90, 1.00). Chest skinfold, systolic and diastolic blood pressure, serum cholesterol, serum triglycerides, plasma glucose, peripheral vascular disease, forced expiratory volume for 1 second, and smoking were not associated with risk of stroke while adjusting for age, sex, and race.

After controlling for all covariates simultaneously and substituting the variable high blood pressure for both systolic and diastolic blood pressure, we found that the study variables ponderal index and chest skinfold showed no independent effect on the rate of stroke (Table 4). Black women 70 years of age or older continued to experience a substantially higher rate of stroke than did White men less than 70 years old. The rate of stroke among individuals with hypertensive heart disease was more than twice that of healthier individuals; those with diabetes experienced nearly a 70% higher rate. Subjects who met our criteria for high blood pressure had a 30% higher rate of stroke than did subjects without high blood pressure, although this association did not reach statistical significance.

TABLE 3—Risk of Stroke, by Race, Sex, and Age and Based on Simple Logistic Regression Modeling: Chicago Stroke Study

	n	Frequency of Stroke	Crude Risk	Odds Ratio	95% Confidence Interval
Age <70 y					
White men	272	9	.033	1.00	...
Black men	376	25	.066	2.08	0.95, 4.53
White women	221	9	.041	1.24	0.48, 3.24
Black women	311	20	.064	2.01	0.90, 4.51
Age ≥70 y					
White men	316	22	.070	2.19	0.99, 4.85
Black men	360	28	.077	2.46	1.14, 5.31
White women	405	31	.076	2.42	1.13, 5.24
Black women	512	55	.107	3.52	1.71, 7.23

TABLE 4—Associations between Ponderal Index, Chest Skinfold, Selected Cardiovascular Disease Risk Factors, and Stroke Based on Cox Proportional Hazards Models: Chicago Stroke Study

	Model 1		Model 2	
	Relative Risk	95% Confidence Interval	Relative Risk	95% Confidence Interval
Ponderal index	0.96	0.84, 1.08		
Chest skinfold				
<7 mm			1.00	...
7–11.9 mm			0.88	0.58, 1.33
12–18.9 mm			0.99	0.69, 1.44
≥19 mm			0.83	0.56, 1.24
Black women aged ≥70 y	2.38	1.16, 4.89	2.39	1.16, 4.91
Hypertensive heart disease	2.18	1.58, 2.99	2.17	1.58, 2.98
Diabetes	1.66	1.22, 2.27	1.66	1.22, 2.27
High blood pressure	1.27	0.94, 1.73	1.28	0.94, 1.74

Note. Two separate models were considered, one with the ponderal index and the other with chest skinfold.

Discussion

Several longitudinal studies have reported overall adiposity and, specifically, adiposity distributed around the trunk to be significant and independent risk factors for cardiovascular disease.[7–10] Whether this excess risk contributed by adiposity continues into older adulthood is not clear.

The main hypothesis of this study was not substantiated. Overall adiposity and truncal adiposity did not serve as independent predictors of stroke in our study population. The ponderal index showed a marginally significant association with stroke incidence in the simple analysis but failed to retain statistical significance in the presence of the other covariates. Black women 70 years of age or older and individuals with preexisting hypertensive heart disease and diabetes continued to demonstrate an excess rate of stroke in the multivariable analysis. These findings suggest that adiposity exerted its effects on stroke through its association with stroke-related disorders and risk factors among our older population rather than through a direct, independent association.

Three longitudinal studies[24,29,30] found measures of overall adiposity to be associated with an increased risk of stroke among older populations. Whether or not these associations were independent of such factors as hypertension or diabetes is unclear. There is some evidence from the Framingham study[31] that relative weight is associated with increased risk of stroke among women only, independent of blood pressure. Among subjects in the Evans County study,[22] body mass index was an independent predictor of stroke mortality only among White women of lower socioeconomic status.

The Framingham study[10] also found a positive relationship between its indicator of truncal adiposity (subscapular skinfold thickness) and 28-year incidence of coronary heart disease that was independent of body mass index. Other studies have found subscapular skinfold thickness, or a combination of skinfold measures, to be associated with risk factors for cardiovascular disease such as blood pressure, serum lipids, and serum glucose.[32,33]

The causal mechanisms for the relationship between truncal adiposity and cardiovascular disease are not fully understood. An android type of fat patterning, characterized by an excess of upper-body fat relative to lower-body fat and composed of hypertrophied fat cells,[13] is related to various hemodynamic and metabolic complications, such as hyperlipidemia, hyperinsulinemia, glucose intolerance, and sodium retention.[14–20] The consequences of these various aberrations for conditions such as diabetes, hypertension, and subsequent cardiovascular disease seem clear, although evidence for a direct or indirect causal pathway has not been confirmed.

Adiposity may be important to disease conditions such as hypertensive heart disease or diabetes but may have explained nothing over and above these powerful predictors of stroke among our older study population. Moreover, by controlling for the variables through which obesity mediates its effect on car-

diovascular disease, we may have underestimated the effect of obesity.

These results from the Chicago Stroke Study data also suggest that the excess cardiovascular risk associated with adiposity in middle age loses its impact in older ages.[34] Several studies have identified age as another important modifying variable of stroke incidence.[35,36] While adiposity was associated with traditional cardiovascular disease risk factors, such as blood pressure, serum lipid levels, glucose levels, and smoking, these correlations were weaker than those found among younger populations.[37,38] Moreover, these traditional cardiovascular disease risk factors were not significantly related to the risk of stroke among our older population in the presence of age, race, and sex; however, their disease sequelae (hypertensive heart disease and diabetes) were. The finding that neither systolic nor diastolic blood pressure was associated with stroke in the presence of age, sex, and race alone suggests that target organ damage may be necessary to elevate risk of stroke among a cohort in which mechanisms of selective survival are operating. More knowledge is needed about the natural history of blood pressure, hypertension, and cardiovascular disease with aging.

Criticisms of other studies finding negative results between adiposity and cardiovascular disease among older adult populations have focused on the failure of these studies to control for such suspected confounders as smoking, preexisting disease, antihypertensive medication, and early mortality.[39] Our analysis took these factors into account and therefore can rule out their attenuating effect on the adiposity and stroke relationship in our study population.

Conclusion

Control of hypertension and diabetes continues to be important among older adults. Since excess adiposity seems to exert its influence on the risk of stroke through its association with these preexisting disorders, control of excess weight and fat remains an important concern among this age group as well. Prevention programs aimed at weight and hypertension control (through diet and increasing physical activity) would seem most efficacious in lowering cardiovascular and cerebrovascular disease risk and need to be made accessible to all segments of our population. □

Planning Themes in the Journal: A Call for Papers

We are engaged in a small experiment. For three upcoming issues, we have announced the featured theme ahead of time. To ensure the submission of a sufficient number of papers, we invite potential authors among our readers to submit papers relevant to the chosen topics by the dates announced.

In recent volumes, Journal editors have successfully assembled themes out of the material on hand. Reader response has been positive. Theme issues announced in advance will be more coherent than those created from random submissions if they attract the number of authors we hope for. They will also enable us to indicate the Journal's interest in neglected areas that authors may not see as high on our agenda now.

Our first call for papers, announcing three topics, was published in the November 1992 issue of the Journal. Papers submitted for the first theme, "Children: Societal and Individual Violence, Injury, and Abuse" (deadline was April 1, 1993), have been reviewed; those revised and accepted will be published in the April 1994 issue. Papers submitted for the second theme, "Age and Aging: Epidemiology, Health Care, and General Public Health" (deadline was August 1, 1993), have been reviewed; those revised and accepted will be published in mid-1994. (Please note that submissions on these themes are welcome at any time.)

The third theme and its deadline for submission is as follows:

Primary Care and Public Health
Submissions due February 1, 1994

Before sending us your manuscript, please consult "What *AJPH* Authors Should Know," published in each issue of the Journal and available from the office, for standards of submission and address.

Estimating Clinical Morbidity Due to Ischemic Heart Disease and Congestive Heart Failure: The Future Rise of Heart Failure

ABSTRACT

Objectives. Many developed countries have seen declining mortality rates for heart disease, together with an alleged decline in incidence and a seemingly paradoxical increase in health care demands. This paper presents a model for forecasting the plausible evolution of heart disease morbidity.

Methods. The simulation model combines data from different sources. It generates acute coronary event and mortality rates from published data on incidences, recurrences, and lethalities of different heart disease conditions and interventions. Forecasts are based on plausible scenarios for declining incidence and increasing survival.

Results. Mortality is postponed more than incidence. Prevalence rates of morbidity will decrease among the young and middle-aged but increase among the elderly. As the milder disease states act as risk factors for the more severe states, effects will culminate in the most severe disease states with a disproportionate increase in older people.

Conclusions. Increasing health care needs in the face of declining mortality rates are no contradiction, but reflect a tradeoff of mortality for morbidity. The aging of the population will accentuate this morbidity increase. (*Am J Public Health.* 1994;84: 20–28)

Luc Bonneux, MD, MSc, Jan J. Barendregt, MA, Karin Meeter, MD, PhD, Gouke J. Bonsel, MD, PhD, and Paul J. van der Maas, MD, PhD

Introduction

Heart disease, comprising ischemic heart disease and congestive heart failure, is not only the leading cause of death and lost life expectancy in most Western countries but also one of the most important causes of morbidity and health care costs.[1] After a period of increasing mortality during the 1950s and 1960s, Western countries have witnessed a dramatic decline of ischemic heart disease mortality (age-adjusted), with the United States taking the lead.[2] Though the dynamics are not completely understood, time trends in known risk factors for ischemic heart disease (hypertension, cholesterol, smoking) in Western countries indicate a clear decline.[3–5] Therefore it is reasonable to attribute at least part of this decrease in mortality to a decrease in incidence.

The observed sharp decline in mortality, together with the probable decline in incidence, leads one to expect a concomitant decrease in health care utilization. In reality, however, health care providers all over the Western world are facing increases in demand. After the introduction of percutaneous transluminal coronary angioplasties, utilization of these procedures increased almost exponentially, while the growth in utilization of coronary artery bypass graft surgery merely slowed.[6] Viewed superficially, the observed increases in demand are incongruent with the supposed decrease in need.

But is need truly decreasing? Basic epidemiologic theory teaches us that if mortality slows faster than incidence, prevalence will increase. Although the Framingham Heart Study has shown a small decline in incidence, a strong increase in prevalence has been observed, indicative of a survival gain.[3] This improved prognosis has been caused partly by improved risk factor distributions, but medical therapy has also contributed.[7,8] Recently, beta-blocking agents, platelet aggregation inhibitors, coronary artery bypass graft surgery, and angiotensine converting enzyme inhibitors have been applied in chronic therapy and thrombolytic therapy has been applied in emergencies. All have been proven effective in randomized controlled trials meeting high standards.[9–11] If trends in risk factors and survival remain favorable, the further decrease in incidence and mortality of ischemic heart disease is likely to be accompanied by a continuing increase in prevalence. In Western countries, the increased prevalence will be accentuated by the aging of the baby boom generation born after World War II. This cohort will soon reach middle age with its concomitant heart disease risks: the increase in age-specific prevalence will be accompanied by an increase in sheer size of the older age groups.

To make a quantitative analysis of the dynamics of the heart disease epidemic, we developed a simulation model for the most important manifestations of ischemic heart disease and congestive heart failure. Available information from the medical literature was combined with data obtained from mortality and morbid-

ity registers. We explored the future of heart disease morbidity in the Netherlands in different scenarios.

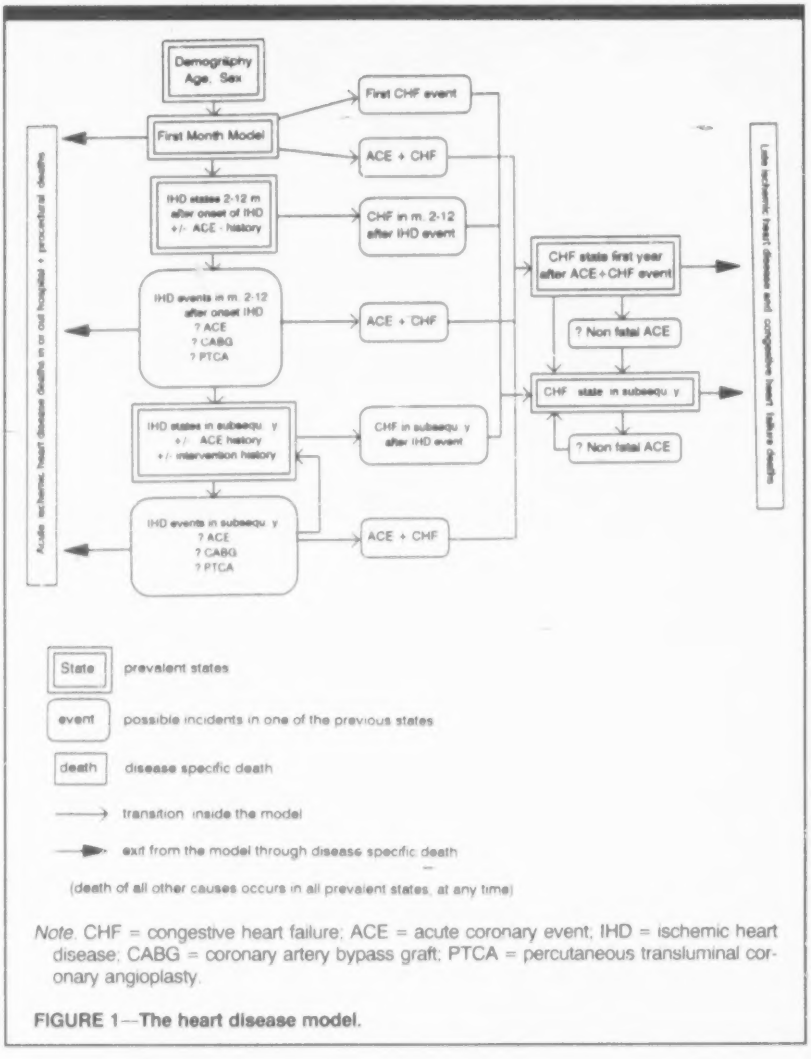
Methods

Model Structure

The deterministic state transition model used divides the population under study (here the entire Dutch population) into homogeneous subpopulations called states, defined by age, sex, and disease history. Each year, the population "ages" by 1 year and the states are updated. Transitions from one state to another are governed by transition probabilities, extracted from registries and literature. Transition probabilities are independent from the preceding states and depend only on the current state (Markov chain assumption).[12] The structure of the model resembles the Coronary Heart Disease Policy Model of Weinstein et al., but we have excluded cardiac arrest as a prevalent state and included congestive heart failure.[13]

The morbidity model consists of three main sectors: the first-month model, the ischemic heart disease model, and the congestive heart failure model. Persons developing heart disease, the rate of which is dependent on age and sex, move into the first-month model, which characterizes the initial event and its immediate sequelae during the first 30 days following the onset of disease. Persons in whom congestive heart failure forms the first heart disease event move directly into the appropriate model. Survivors of the first 30 days enter the ischemic heart disease model or the congestive heart failure model that describes the remaining 11 months of the first year and all subsequent years. Persons with ischemic heart disease can move into the congestive heart failure model, but not vice versa. Death from heart disease is modeled through the specific transition probabilities of the model. In all prevalent states, persons are subjected to an additional risk of death from all other causes, corrected for heart disease, that is based on national life tables.[14]

The first-month model covers the month immediately after the initial cardiac disease event (Figure 1). This event may be angina pectoris, an acute coronary event (an acute myocardial infarction or cardiac arrest), or congestive heart failure. Persons suffering a first acute coronary event may die before reaching a health care facility (deaths before admission).



Demography
Age, Sex
First Month Model
First CHF event
ACE + CHF
IHD states 2-12 m after onset of IHD +/- ACE - history
CHF in m. 2-12 after IHD event
IHD events in m. 2-12 after onset IHD ? ACE ? CABG ? PTCA
ACE + CHF
IHD states in subsequ. y +/- ACE history +/- intervention history

IHD events in subsequ. y ? ACE ? CABG ? PTCA
ACE + CHF
CHF state first year after ACE+CHF event
? Non fatal ACE
CHF state in subsequ. y
? Non fatal ACE
Acute ischemic heart disease deaths in or out hospital + precardial deaths
Late ischemic heart disease and congestive heart failure deaths
State
prevalent states
event
possible incidents in one of the previous states
death
disease specific death
transition inside the model
exit from the model through disease specific death
(death of all other causes occurs in all prevalent states, at any time)

Note. CHF = congestive heart failure; ACE = acute coronary event; IHD = ischemic heart disease; CABG = coronary artery bypass graft; PTCA = percutaneous transluminal coronary angioplasty.

FIGURE 1—The heart disease model.

Once taken into care, they are subjected to a further death risk (deaths in hospital). If the person survives the coronary event, the pump function of the heart may be permanently impaired. Patients with heart failure after an acute myocardial infarction enter the congestive heart failure model; the others move into the ischemic heart disease model. Persons with a first diagnosis of uncomplicated angina pectoris or congestive heart failure proceed to the ischemic heart disease and congestive heart failure models, respectively.

On entry, the ischemic heart disease model distinguishes between angina pectoris and acute coronary event states. Conditional on these states, patients face possible new events in the 2 to 12 months after the first incident. These events range from acute coronary events to coronary artery bypass grafts to percutaneous transluminal coronary angioplasties to all possible combinations of these. Each combination of events in a state has a probability of sudden death from ischemic heart disease dependent on the current event, the current state (and therefore the ischemic heart disease history), and the patient's age and sex. The patients also risk heart failure as a sequel of an acute coronary event ("ACE + CHF" in the figure) or as a consequence of chronic ischemic damage; these patients move into the congestive heart failure model. If none of the above occurs, patients will remain in the ischemic heart disease model.

After this first year, patients remaining in the ischemic heart disease model are reclassified into four new states, conditional on previous disease history. These states are described by the presence or absence of an acute coronary event or an intervention. These patients face the same events as in the previous year. At the end of each subsequent model year, persons

TABLE 1—Transition Probabilities for the Age Group 60 through 64 Years

	Men, %	Women, %
First incidence in the total population		
ACE	0.80	0.26
AP	0.47	0.30
CHF	0.20	0.09
Yearly probability of an ACE in the diseased population		
In the population with a history of ACE		
Before no intervention in y 1	5.3	5.3
Before PTCA in y 1	7.1	7.1
Before CABG in y 1	10.7	10.7
After CHF after ACE in y 1	20.5	19.4
After no intervention in y > 1	2.8	2.8
After any intervention in y > 1	4.3	4.3
After CHF in y > 1	7.3	6.2
In the population with a history of uncomplicated AP		
Before no intervention in y 1	1.5	0.6
Before PTCA in y 1	3.7	3.7
Before CABG in y 1	5.5	5.5
After no intervention in y > 1	1.5	0.7
After any intervention in y > 1	2.2	2.2

In y 1 after AP	15.9	8.8
In y > 1 after AP	3.2	0.6
PTCA		
In y 1 after ACE	2.6	1.9
In y > 1 after ACE	0.5	0.4
In y 1 after AP	3.9	2.9
In y > 1 after AP	0.8	0.8
Mortality rates		
Heart disease		
After ACE in mo 1		
First ACE, before admission	17.4	18.0
First ACE, inside hospital	8.4	11.0
Recurrent ACE, before admission	24.0	24.8
Recurrent ACE, inside hospital	12.7	16.5
Recurrent ACE after CHF, before admission	47.1	44.0
Recurrent ACE after CHF, inside hospital	18.9	22.0
Operative mortality after first CABG	1.4	3.0
Operative mortality after recurrent CABG	3.4	3.4
Procedural mortality after PTCA	0.7	0.7
After CHF after ACE in mo 2–11	19.9	17.9
After CHF in y > 1	13.0	11.0
All other causes of death in all states	1.14	0.64

Note. ACE = acute coronary event (including acute myocardial infarction, unstable angina pectoris, and cardiac arrest); AP = uncomplicated angina pectoris; CHF = congestive heart failure; CABG = coronary artery bypass grafting; PTCA = percutaneous transluminal coronary angiography; in y > 1 = in the years subsequent to the first year after an event.

"age" 1 year and are reassigned to states that reflect their updated history.

Persons with heart failure after an acute myocardial infarction face a high risk of dying during the first year.[15] If they survive the first year, they move to the congestive heart failure state describing the subsequent years, where they will stay until death; this state is called "chronic" to distinguish it from the first critical year following such a complicated infarction. In these "chronic" years, the model assumes that mortality rates are lower. All other patients developing heart failure immediately enter the chronic congestive heart failure state.

Although nonfatal acute coronary events are possible in the congestive heart failure state, such events no longer effect any change in the assigned state. Patients in the congestive heart failure state face an annual probability of death due to cardiovascular causes that may be classified as acute myocardial infarction (ICD 410–411), chronic ischemic heart disease (ICD 412–414), congestive heart failure (ICD 428–429), or stroke (ICD 430–438).[16] We have incorporated stroke as a specific cause of death because the Framingham Heart Study showed that, because of common risk factors (hypertension and diabetes), congestive heart failure is associated with increased rates of stroke and death from stroke.[17]

Incidence and Recurrence Rates

Reliable and recent incidence data on heart disease are not available in the Netherlands. Incidence figures have been estimated by an iterative nonlinear procedure from observed numbers of events (acute myocardial infarctions, ischemic heart disease deaths, interventions) and externally estimated transition probabilities.[18] In this section we give a brief account of how they were derived. The transition probability matrix for a typical age group (60 through 64 years) is furnished in Table 1. The complete transition matrices and a more detailed account of references are available from the authors on request.

Total numbers of admissions for acute myocardial infarction (ICD 410), total numbers of hospital deaths, and total numbers of interventions by age and sex are available from the nationwide hospital register.[19–22] Patients with symptomatic infarctions who are not admitted to hospital (6%; in the Netherlands, this group is limited to the oldest age groups) are added.[23] A constant ratio for the probability of dying before hospital admission versus dying inside the hospital from an acute coronary event is assumed.[20,21,24,25]

Reported probabilities of recurrent acute coronary events vary widely, from 2% to 13% and more per year, depending on age, case mix, and selection criteria.[13,26–30] We have assumed that ischemic heart disease patients without congestive heart failure have a first annual probability of a recurrent acute coronary event of 0.062. This probability is consistent with the estimate of Weinstein et al. of 0.078, in which patients with congestive heart failure are included.[13,31] Recurrence rates are strongly age dependent. We assume the age distribution to be identical to the known age distribution of a first acute coronary event in the reference population. First acute coronary events after a history

of angina pectoris were modeled on the basis of data derived from the Framingham study, which showed that male patients with angina pectoris, who have suffered no previous acute myocardial infarction have a relative risk of 0.54 compared with male patients with a previous acute myocardial infarction.[32] Female patients with angina pectoris have a relative risk of 0.45 compared with male patients.[32]

Patients eligible for coronary artery bypass graft surgery run a risk for recurrent events that is twice as high as that for patients who are not eligible.[31,33–35] Coronary artery bypass graft surgery reduces hazard rates by 20%.[36,37] Lacking data on the effectiveness of percutaneous transluminal coronary angioplasty, we assumed the relative risk for recurrent acute coronary events to be 1.5, with a rate reduction of 10%.

Intervention Rates

Intervention rates are known to vary widely from country to country and even from hospital to hospital.[38,39] We have used age- and sex-specific nationwide output data and assumed constant proportional relations between states to estimate the numbers of interventions in each state. The risk of an intervention after uncomplicated angina pectoris vs the risk of an intervention after an acute coronary event is 1.4: 35% of patients with a history of an acute coronary event are potentially eligible for an intervention, compared with 50% in uncomplicated angina.[40,41] The risk of undergoing an intervention in the first year after an ischemic heart disease event vs the risk in subsequent years was taken to be 5.[42] The annual probabilities of having a subsequent intervention after a first intervention are 1.0% (coronary artery bypass graft) and 0.5% (percutaneous transluminal coronary angioplasty).[43] For every 10 successful percutaneous transluminal coronary angioplasties, another 4 are considered to be unsuccessful because of restenosis.[44] If both a coronary artery bypass graft and percutaneous transluminal coronary angioplasty occur in the same year in the same patient, the percutaneous transluminal coronary angioplasty is ignored.

Heart Failure

Heart failure due to ischemic heart disease is caused by acute events or by chronic ischemic damage. Eighteen percent of ischemic heart disease patients survive an acute myocardial infarction with irreversible heart failure as a sequel.[33,34] The distribution by age, sex, and previous ischemic heart disease history is assumed to be the same as the distribution of in-hospital mortality by age, sex, and previous ischemic heart disease history after an acute myocardial infarction. The annual probabilities of developing congestive heart failure, given a history of ischemic heart disease, were estimated from the Framingham Heart Study data.[17] We obtained the published annual event rates of 1.5% given an uncomplicated angina pectoris history and 3.0% given a history of an acute coronary event and adjusted to allow for the number of acute cases caused by an acute coronary event. The age distribution was calculated by applying relative risks of 3.0 (angina pectoris) and 5.0 (acute myocardial infarction) to the age-specific incidence data taken from the Framingham study.[17]

The incidence rates of congestive heart failure for persons without a history of ischemic heart disease are calculated by assuming that persons in whom congestive heart failure is the certified cause of death survived their first diagnosis of congestive heart failure for 5 (males) to 7 (females) years.[11,12,15,17]

Heart Disease Mortality

The total age- and sex-specific in-hospital mortality rates following acute coronary events and interventions are known in the Netherlands.[20,22] The relative risk of dying after a subsequent vs a first acute coronary event was taken to be 1.5.[13,28,45] Publications are available in which the figures on mortality due to a subsequent vs a first coronary artery bypass graft operation are given.[46] The relative risk of death due to percutaneous transluminal coronary angioplasty vs coronary artery bypass graft surgery is 0.5.[47,48] Procedural mortality due to a subsequent or a first percutaneous transluminal coronary angioplasty is taken to be the same.

The risk of death during the first year after acute myocardial infarction followed by congestive heart failure was assumed to be 25%; the distribution by age was constructed by exponential interpolation and extrapolation of data taken from Ahnve et al.[34] The annual mortality risk of heart failure during the subsequent years is assumed to be constant: 10% for females and 13% for males.[15,17,33,34] Of all deaths caused directly or indirectly by heart failure, 25% (female) and 37% (male) are attributable to recurring ischemic heart events and another 25% (males) and 35% (females) are attributable to stroke (and hence to noncardiac disease).[17] The figures for nonfatal acute coronary events in persons with heart failure are estimated by assuming a case fatality of 60%.

All persons in all states are subject to the risk of dying of other diseases, adjusted to allow for the causes of death under study and based on Dutch life tables.

Results

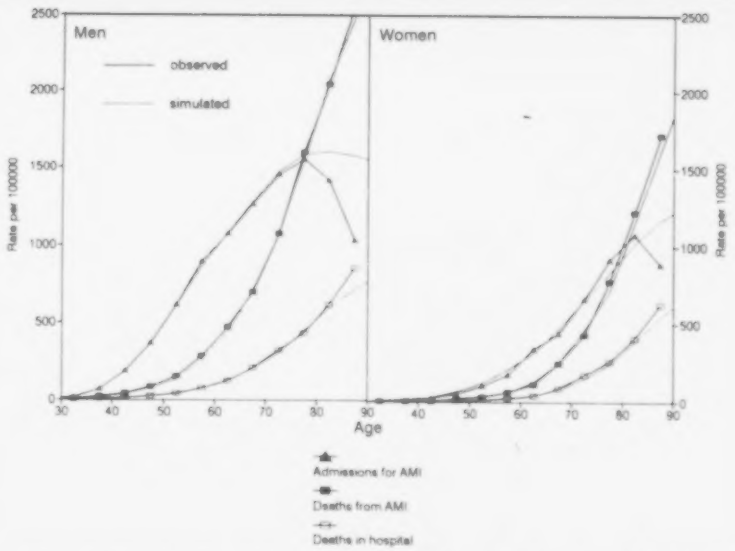
Calculated Estimates for 1985

Figure 2 shows the observed and simulated events of acute myocardial infarction: total admissions and deaths in and outside the hospital, by age and sex. The model closely reproduces the observed data. The gap between simulated and observed rates in the older age groups represents persons with recognized acute myocardial infarctions who are not admitted to a hospital. Calculated prevalences of heart disease by age and sex are shown in Figure 3. Heart disease is more concentrated in the oldest age groups in women, whereas the burden of morbidity in the male population is already high at middle age. The leveling off and decrease by age in the prevalence of clinical ischemic heart disease in men shown in the figure is caused by the steep rise in the incidence of congestive heart failure and sudden cardiac death, reducing clinical ischemic heart disease incidence. Prevalence of all heart disease reaches 25% in the age groups 70 through 74 years (men) and 80 through 84 years (women). Women suffer relatively more often than men from angina pectoris and congestive heart failure, but less often from severe ischemic heart disease. This pattern has been confirmed time and again in many surveys.[32,49,50]

Projections for 1985–2010

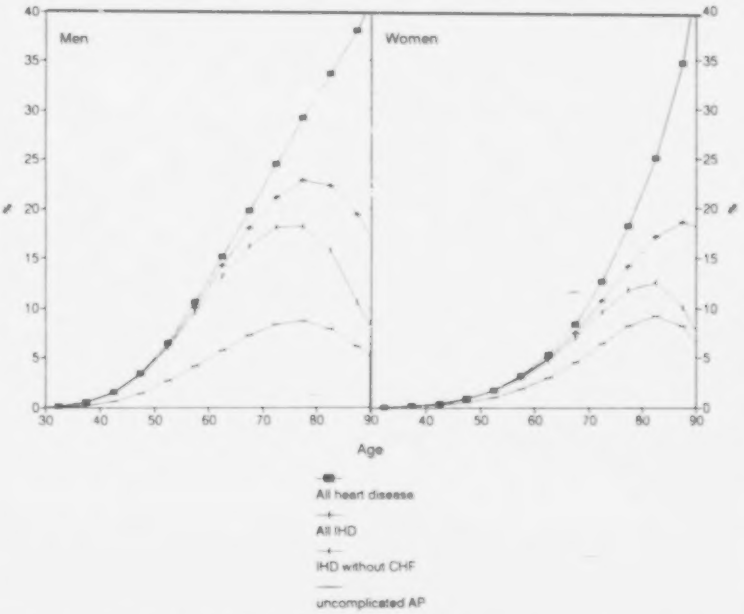
Disease-specific mortality is the direct result of incidence and survival. If two of these elements are known, the third can be calculated. Because the decline in ischemic heart disease mortality that has been observed since 1975 is indisputable, we postulated an ongoing decline of this mortality into the near future. We provide three plausible scenarios, based on varying assumptions of further decreasing incidence rates and improving prognoses (see Table 2).

The reference scenario, based on the Framingham Heart Study, supposes that one third of the mortality decline is explained by a decline in incidence (−1.0% per year) and that two thirds is explained



Note. "Admissions for AMI" are the rates of patients discharged with a primary diagnosis of acute myocardial infarction (ICD 410). "Deaths in hospital" are the rates of patients with the same diagnosis dying in hospital.[20] "Deaths from AMI" are the total rates of death from acute myocardial infarction (ICD 410).[21] The solid lines with symbols show observed numbers; the dotted lines represent the simulation by the heart disease model.

FIGURE 2—Observed and simulated events in 1985.



Note. "Uncomplicated AP" is defined as angina pectoris only, without a history of acute myocardial infarction. "IHD without CHF" describes all patients with a history of ischemic heart disease but without congestive heart failure. "All IHD" comprises all ischemic heart disease, including patients who developed congestive heart failure after ischemic heart disease. "All heart disease" summarizes all three conditions. The difference between all heart disease and all ischemic heart disease shows the prevalence of congestive heart failure.

FIGURE 3—Cumulative prevalences of heart disease, by age and sex, the Netherlands, 1985.

by an increase in survival.[3,4,8,9,26,51] In an extreme low-incidence-change scenario, we assume that the incidence decrease is even less: −0.5% per year. This is the magnitude of change predicted by a risk factor model, based on changes in risk factor prevalences in the Netherlands.[5] In an extreme high-incidence-change scenario, we assume a high decrease in incidence (−1.7% per year).

We have projected these trends over the period 1985 through 2010 to juxtapose the effects of demographic and epidemiologic change.

The results are summarized in Figures 4 through 6 and Table 3. Figure 4 shows how the decreasing incidence, together with the increase in survival, results in lower prevalence rates in the young and increasing prevalence rates in older age groups. In the youngest (30- to 39-year-old) age group, the decrease will be about 25%; in the oldest old (85 years and older), prevalence will increase by 20% for men and 10% for women. Superimposing the population projections on these figures results in a completely different picture, which is shown in the same figure. The movement of the postwar baby boom generation into middle age and the sharp increase in the number of the very elderly is clearly revealed. Together with the projected increase in prevalence rates, this demographic change will result in a steep climb in the number of heart disease patients in the oldest age groups. Hence, while epidemiological changes in cardiovascular disease will result in an increase of 10% to 20% in prevalence rates for the oldest old (85 years and older), the absolute number of patients will more than double.

Figures 5 and 6 show the projected changes in age-specific prevalences for different types of ischemic heart disease; Figure 5 shows the relative changes in rates and Figure 6 shows the absolute changes in numbers. The change in age-specific rates for all ischemic heart disease combined is the same as in Figure 4.

Figure 5 shows a relative increase of severe ischemic heart disease. Milder stages of the disease act as a risk factor for the more severe stages. If survival increases in all disease stages, effects will culminate in the most serious stages: as more patients stay alive with ischemic heart disease, more will have the opportunity to develop congestive heart failure. Figure 6 shows the changes in absolute terms: the relative decrease of prevalence at younger ages has hardly any impact because of the low number of patients with

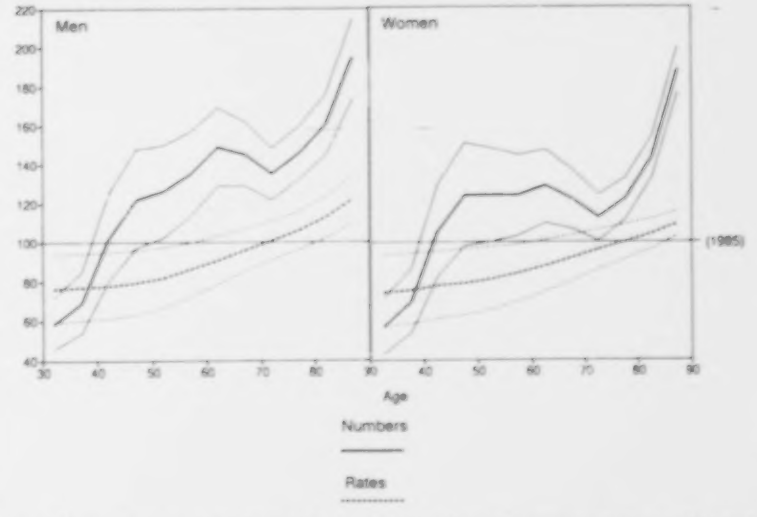
ischemic heart disease at early ages. However, the combination of aging and increasing survival of heart disease leads to a flood of middle-aged men with ischemic heart disease followed by a slower wave of elderly persons with heart failure.

Table 3 shows expected changes in age-standardized rates, using the European Standard Population as the standard, and in absolute numbers, combining the rates with the expected population dynamics in the Netherlands. The mortality decline (observed between 1975 and 1990 and projected over the next 20 years) is so strong that it will be evident even when expressed in absolute numbers. Although the assumed decline in incidence of first myocardial infarctions, which accounts for one third of the decline in mortality, is too small to counteract the aging of the Dutch population, the rate of all myocardial infarctions together will nevertheless decrease substantially. This decrease is the result of the combined decline in incidence and recurrence; the better survival, on the other hand, through which the number of patients at higher risk of recurrent infarctions is increased, is not strong enough to counteract this decline. Because more patients will stay alive and at risk for interventions and reinterventions and because of the aging of the population, the need for coronary artery bypass graft surgery and percutaneous transluminal coronary angioplasty will increase by 1% per year (range: 0.4%–1.6%). The age-standardized prevalence ratios for milder ischemic heart disease tend to decrease, but those for ischemic heart disease complicated by congestive heart failure increase strongly: in absolute numbers, a growth of more than 70% is to be expected.

TABLE 2—Annual Percentage Changes Postulated in Three Scenarios for the Period 1985 through 2010

	Men	Women
	Reference (Extremes)	Reference (Extremes)
Incidence	−1.1 (−1.7, −0.6)	−0.9 (−1.4, −0.5)
Mortality before admission	−1.2 (−0.9, −1.4)	−0.7 (−0.5, −0.8)
Mortality within first month after admission	−2.1 (−1.6, −2.5)	−1.3 (−1.0, −1.6)
Late mortality	−1.8 (−1.4, −2.1)	−1.6 (−1.4, −2.1)
Recurrence	−3.1 (−2.3, −4.7)	−1.9 (−1.4, −2.9)
Ischemic heart disease mortality	−2.4	−2.0

Note. It is assumed that the mortality decline observed between 1975 and 1990 remains equal in all scenarios.



Note. Dashed lines show the expected index of change in prevalence rates between 1985 and 2010 (prevalence in 2010 divided by prevalence in 1985 multiplied by 100). Solid lines indicate the change in absolute numbers, showing the force of demography. The heavier lines indicate the reference scenario; the thinner lines indicate the extreme scenarios.

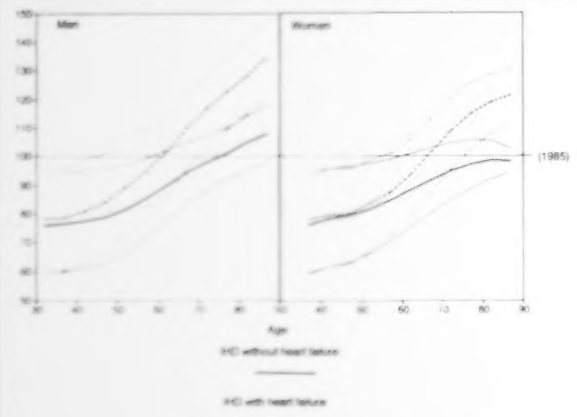
FIGURE 4—Expected changes in absolute and relative prevalence of patients with ischemic heart disease, the Netherlands, 2010 compared with 1985.

Discussion

Simulation modeling provides quantitative insight into epidemiological and public health dynamics and potential future developments. The information needed for these models can never be supplied by a single data source. Combining data from different sources is therefore appropriate, and the use of state-transition models provides a simple and comprehensible means of doing so. The methods used are relatively easy to understand. The parameters of the model are meaningful to physicians and the results are interpretable by health care providers, who are the principal users of these results.

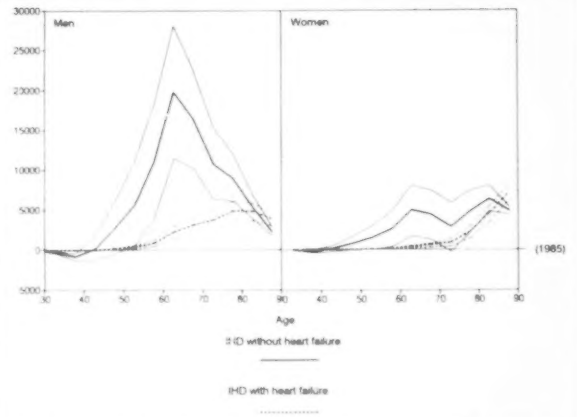
Nevertheless, to interpret results correctly, the limitations of this kind of modeling should be understood. A number of simplifying assumptions are always necessary to keep the model, and more particularly the number of parameters to be estimated, manageable. We included certain disease manifestations and excluded others. Unlike Weinstein et al., we excluded cardiac arrest as a prevalent state but included congestive heart failure. Cardiac arrest is highly lethal, and no major error is introduced by mixing the history of those surviving an acute myocardial infarction with that of a few survivors of cardiac arrest. On the other hand, the inclusion of congestive heart failure takes into account an important cause of chronic and severe morbidity. Modeling the dynamics of and the relations between these different types and levels of morbidity should result in a more realistic estimate of future health care needs.

We used registered admissions for acute myocardial infarction (ICD 410), deaths from ischemic heart disease (ICD 410–414) and congestive heart failure (ICD 428–429), and transition probabilities extracted from multiple sources to estimate incidences. This complicates the assessment of validity, which is the most important problem of this or any other model with such complexity. The model output reflects state-of-the-art clinical evidence, closely simulating present hospitalization, intervention, and mortality rates (see Fig-



Note. Solid lines indicate the relative changes in number of ischemic heart disease patients without heart failure; dashed lines indicate those with heart failure (age-specific prevalences in 2010 divided by the same prevalences in 1985 multiplied by 100). The heavier lines indicate the reference scenario; the thinner lines indicate the extreme scenarios.

FIGURE 5—Expected relative changes in prevalence rates of ischemic heart disease, the Netherlands, 2010 compared with 1985.



Note. Solid lines indicate the absolute changes in number of ischemic heart disease patients without heart failure; dashed lines indicate those with heart failure (age-specific numbers of patients in 2010 minus the same numbers in 1985). The heavier lines indicate the reference scenario; the thinner lines indicate the extreme scenarios.

FIGURE 6—Expected absolute changes in numbers of patients with ischemic heart disease, the Netherlands, 2010 compared with 1985.

TABLE 3—Age-Standardized Rates[a] and Absolute Numbers of Admissions, Interventions, Patients, and Deaths due to Ischemic Heart Disease (IHD) and Congestive Heart Failure (CHF) in the Netherlands, in 1985 and the Projected Index of Change (1985 = 100) in 2010

	1985		Index of Change in 2010 (1985 = 100)	
	Rate	Number	Rate	Number
Men				
ACE incidence	267	16 438	76 (65, 87)	114 (97, 130)
First admissions	214	13 150	80 (67, 93)	119 (100, 139)
Admissions for ACE	352	21 687	67 (60, 73)	100 (90, 108)
CABG	96	5 797	84 (72, 90)	128 (110, 147)
History of AP	1726	106 968	91 (79, 104)	136 (119, 156)
History of ACE	2087	129 149	90 (79, 102)	136 (118, 153)
CHF with history of IHD	575	35 761	118 (104, 131)	170 (149, 189)
CHF without history of IHD	697	41 323	94 (88, 126)	144 (133, 163)
Deaths coded AMI	194	12 045	54[b]	80[b]
Deaths coded chronic IHD or CHF	106	6 422	65[b]	96[b]
Women				
ACE incidence	109	9 507	80 (71, 89)	115 (105, 126)
First admissions	81	6 883	83 (73, 94)	118 (105, 131)
Admissions for ACE	122	10 529	73 (66, 78)	105 (96, 111)
CABG	18	1 302	84 (72, 97)	115 (98, 132)
History of AP	1088	94 635	89 (78, 99)	123 (110, 136)
History of ACE	547	45 195	94 (82, 106)	130 (114, 146)
CHF with history of IHD	294	29 251	115 (103, 125)	169 (153, 183)
CHF without history of IHD	509	50 729	84 (77, 104)	130 (120, 146)
Deaths coded AMI	82	7 889	63[b]	96[b]
Deaths coded chronic IHD or CHF	60	6 036	59[b]	90[b]

Note. The expected rates and numbers can be calculated by multiplying the figures for 1985 by the index of change in 2010 divided by 100. The upper and lower bounds (in parentheses) represent the results of scenarios assuming extremely high or low incidence changes but leading to the same mortality changes as a result of extremely low or high survival changes (see Table 2). ACE = acute coronary event; CABG = coronary artery bypass graft; AP = angina pectoris; AMI = acute myocardial infarction.

[a]Per 100 000; the European Standard Population is used as the standard.

[b]In the calculation of upper and lower bounds, the mortality decline is assumed to remain equal.

ure 2). Its estimated prevalences of clinical disease coincide closely with empirical observations.[49,50,52]

Our forecasts are based on mortality projections. For health care planning purposes, projections of incidence based on past risk factor prevalences are less reliable. First, prevalences of all known risk factors for heart disease are not available; prevalence numbers that are available are often highly inconsistent between studies. For example, estimates of the prevalence of hypertension in Dutchmen aged 50 through 59 years vary from 14.4% to 67%.[5,52] Second, not all risk factors are known or observable; projections based only on known risk factors are bound to underestimate future trends. The assumption that mortality will continue to decline is uncertain, but not implausible. It supposes a progressive change in risk factor distributions, a more widespread use of effective health care interventions in the future, and ongoing technological advances.[3,4,8,9] The level of ischemic heart disease mortality expected in 2010 is comparable to that of 1950 (making allowances for changes in codification). Given the absence of effective therapies in 1950, this is not an extreme result. The reference scenario supposes a decrease in incidence, explaining one third of the mortality decline, based on the Framingham study.[4] Other assumptions about incidence decreases and survival increases within extreme ranges are shown in the alternative

scenarios.[3,4,8] These assumptions influence the absolute magnitude of the expected changes, but not the direction.

Declining incidence rates mean that the onset of disease is postponed but not halted. The delay in occurrence causes a reduction of morbidity in the young, which, however, is canceled out with age. Mortality is deferred to an even greater extent, owing to a combination of the decrease in incidence and improved prognosis. This mortality decrease will be traded off for a steep increase of more severe morbidity in the old.

Changes in demography will prevent a decrease of new cases of heart disease.[13] However, while age-specific incidence rates show a decline, acute myocardial infarction rates will drop more steeply, owing to a reduction in both incidence and recurrence rates; the increasing prevalences are insufficient to cancel these reductions. The reference scenario predicts a decline in acute myocardial infarction rates that will be sufficiently strong to offset population aging; this development has been observed in the Netherlands since 1985.[19–21] But although disease incidence rates are declining, intervention rates will remain unchanged, even assuming that intervention rates per group of patients in a certain disease state remain constant. The reason is that more patients will survive and, on average, survival is longer, resulting in more people in disease states who are eligible for invasive coronary revascularization procedures.

The overall picture emerging from the heart disease scenarios is one of transition from an acute to a more chronic disease: event rates are declining steeply, but the postponed mortality is traded off for increased morbidity and severity of disease among the elderly. This pattern can be observed in hospital admission rates in the Netherlands, in data from the National Health Interview Survey in the United States, and in data from the National Health Survey of Japan.[19,53] All of these data show increasing prevalences of ischemic heart disease. As a consequence, overall health care needs will continue to rise, regardless of declining mortality and incidence.

These calculations, based on empirical observations, shed a new light on Fries' compression of morbidity theory.[54] The compression of morbidity theory hinges on the proposition that the incidence of disease will be postponed more rapidly than mortality. For heart disease, the evidence suggests that the decline of lethality expands the number of years spent with heart disease morbidity, regardless of the incidence postponement. Healthy life expectancy is extended, as expected by Fries and assumed by the scenarios, but contrary to his prediction, total life expectancy is extended even further. Among the middle-aged and elderly, acute heart disease lethality in the Netherlands is high, increasing sharply with age. Obviously, here would appear to be a serious potential for reduction. In 1985, for example, the model calculated that 41% of the 70-year-old men died within 4 weeks of their first acute coronary event.[20–24] In our scenarios 32% (range: 30%–34%) are predicted to die within the same period in the year 2010, which in our view remains a conservative estimate. Because heart disease is concentrated in the older age groups, even small differences in the rates of change in incidence and mortality can have major consequences, particularly now that pushing back mortality has been shown to be counterbalanced by an increase in the more severe stages of heart disease. With short-term case-fatality subsequent to an acute event as high as it is, lowering these rates will remain an important goal of health care intervention. Should this aim be successful, the resulting increase in the number of survivors will boost heart disease morbidity and lengthen life expectancy with disease. Only if health care interventions aimed at reducing mortality subsequent to the event should prove a waste of time and money would no expansion of morbidity be expected. □

Self-Reported Physical Activity in a Rural County: A New York County Health Census

Charles B. Eaton, MD, MS, Anne N. Nafziger, MD, MHS, David S. Strogatz, PhD, and Thomas A. Pearson, MD, PhD, MPH

ABSTRACT

Objectives. Few studies have described physical activity in rural populations. This study describes the frequency, types, and correlates of physical activity in 29 304 free-living adults in a rural county in New York State.

Methods. Self-reported responses about regular physical activity (maintained long enough to work up a sweat) were analyzed from a private household census of Otsego County with an 86.6% response rate.

Results. This survey categorized 46.2% of county residents as sedentary. Walking, the most frequent choice of activity (62% of the women, 36% of the men), increased in frequency with age of respondents whereas cycling, jogging, aerobics, team sports, and swimming (listed in rank order of frequency) generally tended to decrease in frequency with age. Farmers demonstrated an increased amount of "sweat activity" compared with persons in most other occupations.

Conclusions. This descriptive study of physical activity in a rural county shows that sedentary lifestyle is of high prevalence. The high frequency of walking and the gender differences in both the levels and choice of activity suggest that further research and public policy recommendations focus on these issues. (*Am J Public Health.* 1994;84:29–32)

Introduction

For public health programs to be targeted appropriately, information on the types and frequency of physical activity in various groups, such as rural populations, needs to be obtained. Most previous community studies have been performed in urban or suburban settings, not in rural ones.[1–4] Larger national studies have been conducted,[5–11] but only two[5,6] have been analyzed comparing urban vs rural location. Data on risk factors such as physical activity may help explain the usual advantage of rural areas in urban-rural comparisons of coronary heart disease mortality and trends in coronary heart disease mortality over time.[12–15] This paper describes the frequency, types, and correlates of physical activity in a rural population in New York State.

Methods

Door-to-door collection and assistance with completing a private census form led to a 86.6% level of participation rate representing 17 144 out of 19 800 households. The section of the census form giving data about physical activity, self-reported height and weight, and standard sociodemographic information was completed by 33 428 individuals aged 17 years or older. To assess levels of physical activity, respondents were asked, "At least once a week, do you engage in any regular activity like brisk walking, jogging, bicycling, etc. long enough to work up a sweat? (No, Yes) If yes, how many times a week? _____ Activity _____."

This question, which was derived from Paffenbarger et al.'s[16] original physical activity questionnaire, has been validated by Siconolfi et al.,[17] Kohl et al.,[18] and Washburn et al.[19] and shows correlations with measures of cardiovascular fitness (maximal oxygen consumption [$\dot{V}O_2$ max])[17,18] and high-density lipoprotein cholesterol[19] that are the same as or better than longer questionnaires. The reliability of this question ranges from $r = .60$ to $r = .71$ in women and from $r = .26$ to $r = .36$ in men.[20]

An answer of no to the physical activity question was used to define sedentary behavior; an answer of yes defined nonsedentary behavior. The single activity associated with sweat-related physical activity was categorized into one of 18 types: walking, weight lifting, aerobics/calisthenics, jogging/running, swimming, cycling, gardening, team sports, racquet sports, other aerobics, skiing, dancing, nonaerobic sports, work related, outdoors, farm related, chopping wood, and miscellaneous. Cigarette smoking was evaluated by self-report comparing present vs past smoking or never smoked.

Physical activity was evaluated both as the mean number of times per week participants were involved in "sweat activity" and as the percentage of the population labeled sedentary. Analysis of covariance was used to derive least square means to determine the mean number of times per week of sweat activity, and F tests were

used to determine differences in activity by race, gender, age, marital status, location, level of education, and occupation. A logistic model comparing sedentary with nonsedentary activity was evaluated separately for men and women stratified by age group (young = 17 to 35, middle age = 36 to 65, old = 65 to 89) using dichotomous predictor variables of smoking, having a blue-collar job, being married, and having less than a high school education, with the quetelet index (kg/m^2) evaluated as a continuous variable. All analyses were done using the SAS statistical package.

Results

Levels of Physical Activity

Table 1 categorizes subjects as sedentary and nonsedentary and describes the mean number of times per week participants engage in sweat activity for each sociodemographic descriptor. In this study, 46.2% were sedentary and 53.8% were nonsedentary. Excluding work and examining only leisure-time physical activity reveals that 48.8% were sedentary.

Comparisons of the mean number of times per week participants were involved in sweat activity revealed differences by age, marital status, gender, education (in all cases, $P < .001$), and occupation ($P < .01$) but no differences by race or location. Farmers demonstrated an increased amount of sweat activity compared with persons in most other occupations but had the same percentage of sedentary behavior, suggesting a bimodal distribution.

Types of Physical Activity

As described in Table 2, walking was the most popular activity for men and women in all age groups. For those aged 18 to 35 and 36 to 65, other prevalent types of activity for men were work related and jogging while women chose aerobics. In the oldest age group (65 to 89), men preferred gardening, work-related activity, and nonaerobic activity while women preferred gardening and cycling.

Correlates of Physical Activity

Table 3 reveals the odds ratios and 95% confidence intervals of the multivariable logistic regression for men and women comparing sedentary levels of activity with nonsedentary levels. The correlates of sedentary activity varied with age and gender.

Discussion

This study demonstrates that a large proportion (46.2%) of residents of this rural county were sedentary. Levels of sedentary behavior are higher in this study than both the New York State Behavioral Risk Factor Surveillance System[21] estimates in 1986 (28.4%) and 1987 (36.2%) and the national Behavioral Risk Factor Survey[11] estimates in 1982 (36%). However, the fact that our study questionnaire asked about sweat-related physical activity and not about less intense activity may have overestimated sedentary levels.

Demographic factors such as age, gender, educational attainment, and marital status; behavioral factors such as cigarette smoking; and physiologic factors such as quetelet index are predicative of sedentary activity compared with nonsedentary activity in this rural population and are consistent with studies in other settings.[1,22]

The single type of activity reported in this study is difficult to compare against the multiple activities recorded by other national surveys.[5–11] Nevertheless, walking (49.4%) is clearly the most popular activity in this study, as it is in other surveys,[5–11] and jogging, aerobics, and cycling (approximately 6%) are of similar rank order compared with their standing in national surveys.[5–11]

The high level of physical activity found in this rural county may reflect a more active life-style associated with rural living. This appears particularly true for male farmers, of whom 46.4% were involved four or more times per week in sweat-related activity, which contributed

TABLE 2—Percentage of Men and Women in Each Type[a] of Physical Activity in the Otsego County Health Census, by Age Group

Type of Activity	18 to 35 y		36 to 65 y		65 to 89 y

[a]CI = confidence interval, estimated by logistic regression.

to an average of 1 more sweat day of activity per week in farming compared with other occupations.

The high frequency of walking and the gender differences in both levels and choice of activity suggest that further research and public policy recommendations focus on these issues. The health impacts of the bimodal distribution of farmers' activity patterns with a large percentage involved in sedentary behavior (43%) and a high percentage (46.4%) involved four or more times per week in sweat activity should be explored in future studies. □

New Report from APHA: Access to Care for HIV Disease

The American Public Health Association's Special Initiative on AIDS has recently published the tenth report in its series on acquired immunodeficiency syndrome (AIDS), prepared under the auspices of the APHA AIDS Working Group. The new report is entitled "Access to Care for HIV Disease."

This report summarizes the current knowledge about the manifestations of the disease and the types of services needed by people with HIV. Data on the costs of HIV disease are summarized. Barriers to care are reviewed and strategies for improving access to care are examined.

To date, the series includes these reports:

Report 1: Casual Contact and the Risk of HIV Infection, 2nd ed.
Report 2: Contact Tracing and Partner Notification
Report 3: Illicit Drug Use and HIV Infection, 2nd ed.
Report 4: HIV Antibody Testing
Report 5: Public Health Implications of PCP Prophylaxis
Report 6: Pediatric HIV Infection
Report 7: Public Health Implications of Early Intervention in HIV Disease
Report 8: Women and HIV Disease
Report 9: Tuberculosis and HIV Disease
Report 10: Access to Care for HIV Disease

Each report is $3.50 per copy for APHA members, $5.00 for nonmembers. The complete ten-report series is $45.00 for APHA members, $31.50 for nonmembers. Orders must be prepaid. Order from the American Public Health Association, Publication Sales, Department 5037, Washington, DC 20061-5037; tel. (202) 789-5667.

Car Mass and Fatality Risk: Has the Relationship Changed?

ABSTRACT

Objectives. The finding that the relative safety disadvantage of small compared with large cars is less for post-1980 cars than for pre-1980 cars has stimulated speculation that increasing fuel economy standards would increase fatalities less than previously expected. Fatal crashes between two cars of similar model year were examined to see whether this would be the case.

Methods. Driver fatality risk in relation to car mass was examined with Fatal Accident Reporting System data for crashes between two cars of a specific model year.

Results. The relative risk for driver fatality in the lighter car compared with the other driver's risk in a car 50% heavier was as follows: for 1966 through 1979 cars, the risk was between 3.7 and 5.1; for 1984 cars, 2.6; and for 1990 cars, 4.1.

Conclusions. The results suggest that the lesser mass effect observed for mid-1980s cars occurred because improved crashworthiness features appeared in small cars earlier than in large cars. As all cars are redesigned, the relationship between risk and mass can be expected to approach that observed earlier in pre-1980 cars. If so, future fatality increases from fuel economy increases will be greater than estimated on the basis of mid-1980 data. (*Am J Public Health.* 1994;84:33-36)

Introduction

It has been established for decades that when cars of unequal mass crash into each other, driver fatality risk in the lighter car exceeds that in the heavier car.[1] Recent studies have found that the difference in fatality risk for the same mass difference is greater for older cars (model year 1979 or earlier) than for more recent cars (1980 or later).[2-4] Such findings have contributed to suggestions that car mass is exercising a declining effect on fatality risk and that car mass effects on safety might become less important or even disappear in the future. Such suggestions imply that increasing fuel economy standards would lead to a smaller increase in occupant fatalities than would be expected on the basis of current or earlier data.

The purpose of the present study was to determine whether the relationship between driver fatality risk and car mass has changed and to identify the relationship most likely to apply in the future. We used data from crashes between two cars of unequal mass but similar model year to determine how the ratio of drivers killed in lighter cars to those killed in heavier cars depends on the ratio of the masses of the cars.

Methods

The Fatal Accident Reporting System is a computerized data file maintained by the National Highway Traffic Safety Administration that contains detailed information on all fatal traffic crashes in the United States since January 1, 1975.[5] We used data for two-car crashes between 1975 and 1991 in which at least one of the two drivers was killed and for which the mass and model year of each car were coded.

The method was identical to that used in our previous study,[2] except that the analysis was confined to crashes between cars of specific model year. Ideally, we would have liked to focus exclusively on crashes between cars of the same model year; however, there are generally insufficient data to allow such analyses. Instead, we used a moving average approach that includes cars of the previous and subsequent model years. For example, we include any crash between a 1974, 1975, or 1976 model year car and any other 1974, 1975, or 1976 model year car, thereby increasing the expected number of crashes by a factor of nine. The central value of the moving average—in this example, model year 1975—is the independent variable in the analyses.

For each car crash, a mass ratio, μ', was defined as

$$(1) \qquad \mu' = \frac{\text{Mass of Heavier Car}}{\text{Mass of Lighter Car}}.$$

All crashes for each model year were divided into five categories of μ'; as far as possible, the five categories contained equal numbers of crashes. For each category, a driver fatality ratio, R, was defined as

$$(2) \quad R = \frac{\text{No. Driver Fatalities in Lighter Cars}}{\text{No. Driver Fatalities in Heavier Cars}}.$$

The data were least squares fitted to

$$(3) \qquad \log(R) = u \log(\mu),$$

Note. The graph for model year (MY) 1967 includes all crashes in which a 1966, 1967, or 1968 car crashed into a 1966, 1967, or 1968 car, and so forth. The number of crashes contributing to each plot is indicated by n.

FIGURE 1—Driver fatalities in the lighter car divided by those in the heavier car (R) vs the mass of the heavier car divided by the mass of the lighter car (μ).

where μ is the average of the individual values of μ' in the given category. Each point was weighted in inverse proportion to the variance, σ^2, in $\log(R)$. On the assumption that the fatalities arise from a Poisson process, this variance is given by

$$\sigma^2 = 1/(\text{Fatalities in Lighter Car}) + 1/(\text{Fatalities in Heavier Car}). \quad (4)$$

Because $R \equiv 1$ when $\mu = 1$, the fit involves only one parameter, u; crashes between cars of equal mass are excluded from the analyses. Although the fit is to the log-transformed data, a more convenient form of Equation 3 is

$$R = \mu^u. \quad (5)$$

Results

There are relatively few data for the early model years, because by the time the Fatal Accident Reporting System was begun in 1975, most such cars had already been retired from the road. For the most recent model years there are also relatively few data, because, for example, 1990 cars can contribute only to the data for 1989, 1990, and 1991. It will be another 10 or so years before nearly all crashes involving 1990 cars have occurred.

Because of the moving average approach, the results for specific model years are not independent of the data for adjacent model years. For example, the 1581 crashes for model year 1975 arise from the following specific contributions: (4,4) 225; (4,5) 308; (4,6) 386; (5,5) 137; (5,6) 318; and (6,6) 207 crashes, where (4,4) denotes crashes between model year 1974 cars and model year 1974 cars, and so forth. About 176 crashes (1581/9) are expected between cars of the same model year, and 704 between cars whose model years differed by one. Some of these same crashes also contribute to the estimates for model years 1973, 1974, 1976, and 1977. The error in u, Δu, is one standard error.

Because Equation 5 contains only one parameter, u, the relationship it describes is determined completely by choosing any one illustrative point, such as, say, the one corresponding to one of the cars being 50% heavier than the other ($\mu = 1.5$). This provides a possibly more immediately understandable measure than the essentially equivalent parameter u. For example, for model year 1975 we obtain $R = (1.5)^{4.03} = 5.1$, meaning that if two 1975 cars, one of them weighing 900 kg and the other 1350 kg, crash into each other, the driver of the 900-kg car is 5.1 times as likely to be killed as is the driver of the 1350-kg car. The illustrative mass ratio of 1.5 rather than the value 2 used in earlier work[1,2] was chosen because very few cars made after model year 1980 had as much as twice the mass of other cars of the same model year.

Figure 1 shows R vs μ, as determined by dividing the data into five categories of mass ratio, leading to five plotted points for every model year. The choice of five was based on a compromise between the need to have a sufficient number of crashes in each cell for model years for which there were few data and the need for a sufficient number of points to accurately determine Equation 1. Although a case can be made for letting the number of categories increase for model years with more data, we considered it more important to subject the data for each model year to identical treatment. When there are many data, the estimated values of u and Δu depend hardly at all on the number of categories, in accord with statistical theory. When there are few data and noisy relationships, the parameters are more dependent on the number of categories.

Because the parameters for model years 1989 and 1990, which are based on relatively few data, are central to the study, it is important to establish that they do not depend unduly on the arbitrarily chosen number of analysis categories. Using 3, 4, 5, 6, 7, 8, and 9 categories gives values of u for model year 1989 of 3.04, 3.04, 2.88, 2.76, 2.78, 2.92, and 2.90, re-

spectively; the corresponding values for model year 1990 are 3.17, 3.47, 3.46, 3.26, 3.17, 3.10, and 3.05 (the values used are underlined).

The variation of the parameter u as a function of model year (Figure 2) indicates substantial changes. Of particular note is the strictly monotonic decline from $u = 4.03$ for model year 1975 to $u = 2.33$ for model year 1984. This decline is followed by a rapid rise to $u = 3.46$ by model year 1990. The upward trend indicates that the effect of mass on relative driver fatality risk for future model years may become similar to what it was for earlier model years.

The results above are for all drivers, regardless of safety-belt use. To address whether this fact might introduce confounding effects because safety-belt-use rates have increased, we repeated all analyses, excluding all drivers coded as using safety belts. The results showed no systematic departures from those shown in Figures 1 and 2. However, scatter increased considerably because of smaller sample sizes; the total number of available crashes for model years 1984 through 1990 decreased by more than 50%. Such large reductions occur because if either driver is coded as belted, the crash is excluded. After laws requiring safety-belt use became widespread, nonwearers, especially surviving drivers, were increasingly likely to be incorrectly coded as wearers.[1]

The decision to include drivers regardless of safety-belt use is not expected to have had much effect on the pattern shown in Figure 2. A number of studies using a variety of methodologies have indicated that safety-belt effectiveness does not depend systematically on car mass.[1,2] The study that most closely parallels the present one found a value of u in Equation 5 for unbelted drivers of 3.58, compared with $u = 3.53$ for drivers regardless of belt use and $u = 3.60$ for belted drivers.[2] Even if belt-wearing rates did depend on car mass, this would not affect results much because belt use was relatively low for all model years (27% of fatally injured drivers for model year 1987 were coded as belted, the highest rate for any model year) and belt effectiveness is lower in two-car crashes (30% ± 8%) than in single-car crashes (62% ± 5%).[6] Additional analysis found no important relationships between belt-wearing rates and car mass for any model year.

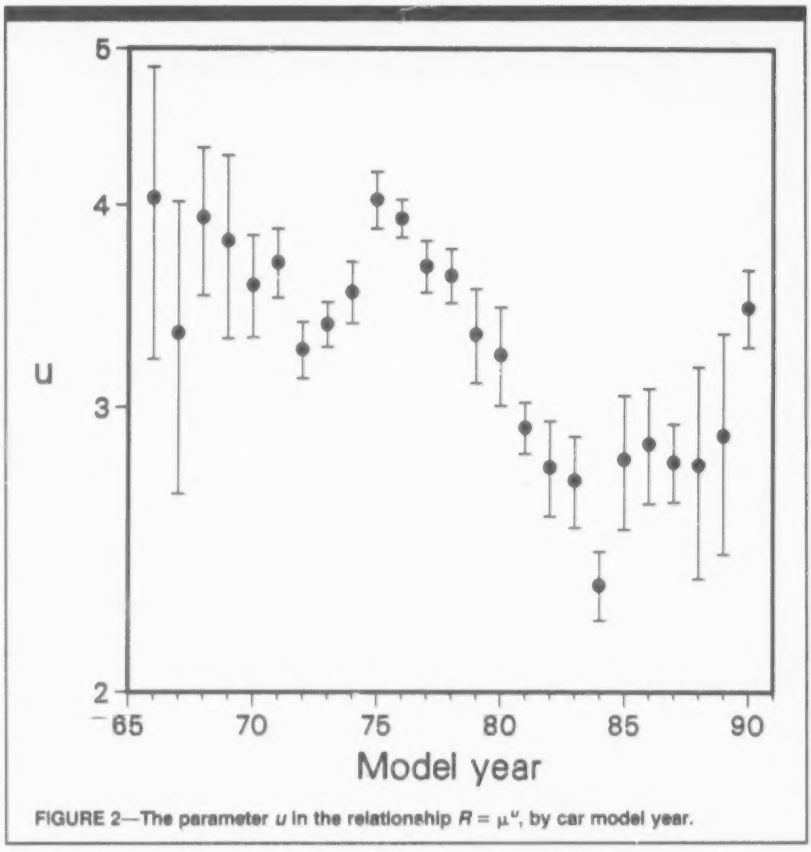

FIGURE 2—The parameter u in the relationship $R = \mu^u$, by car model year.

Discussion

The main purpose of a phenomenological study like the present one is to discover what is happening. Although the results of such studies do not identify the mechanisms leading to the observed effects, they may offer insights into such mechanisms. The following interpretation of Figure 2 is offered as a plausible, though not demonstrated, explanation.

One can interpret a relationship between car mass and fatality risk as including two contributions. First, a contribution is made by what we refer to as the intrinsic effect of mass; included with the intrinsic effect of mass is the effect of size, because these are so strongly correlated.[3] Second, there is a design-related factor. Particular small cars may differ from particular large cars in ways not intrinsically related to their size; for example, if a small car with a rear engine crashed head-on into a large car with a front engine, the relative fatality risk might be larger than if both cars had similarly located engines. Contributions from such differences in some particular early models might generate a small effect on the overall relationships. Apart from this factor, we interpret the car mass effect for pre-1970 cars as reflecting an intrinsic mass effect for a fleet of cars of relatively homogeneous design features but differing in mass. Thus $u \cong 3.7$ represents the mass effect when two cars with similar design features crash into each other.

From the mid-1970s onward, some vehicles were subject to major redesign in which new methods and technologies were applied to manage crash energy dissipation in ways calculated to reduce the injury risk to occupants. Small cars tended to be the first to benefit from such redesign. It thus seems plausible that the lower values of u for mid-1980s cars (for example, $u = 2.3$ for model year 1984) reflect design as well as intrinsic mass effects. Thus the greater risk associated with the smaller car was partially offset by the smaller car's having crashworthiness features not yet incorporated into larger cars. It is also possible that redesign resulted in stiffer structures, which might reduce risks to occupants traveling in the redesigned car but increase risks to occupants in struck cars. This could have a large effect on the fatality ratio, because the numerator would decline while the denominator increased.

As the 1980s proceeded, large cars were subject to the same redesign attention previously devoted to small cars. Thus, as the crashworthiness of the large

cars increased, the relative disparity in risk appeared to be moving back to reflect the same intrinsic mass effect that applied to the earlier model years. At present it is not possible to determine whether values of u will continue to increase and will approach, reach, or exceed their previous levels. However, the trend is consistent with the interpretation that u may approach a new stable value of ~3.7, which represents the intrinsic effect of mass when cars are otherwise of homogeneous design. The much lower u values of the mid-1980s cars were a temporary aberration reflecting effects of both mass and design. Figure 2 shows definitively that the disparity in risk between small and large cars is not continuing to decline and is now clearly greater than the minimum reached for model year 1984.

The results presented here offer a clear interpretation of earlier unexplained findings[2-4] of large differences between older (model year 1979 and earlier) and newer (model year 1980 and later) cars. The u values of 3.53 for older and 2.75 for newer cars[2] are in accord with the values shown in Figure 1 (taking into account weighting by the number of data). Conclusions based on an assumption that the results for model years 1980 and later would apply into the future underestimate the effect of mass on safety. The replacement of heavier cars by lighter cars is expected to result in an increase in fatalities substantially greater than was previously estimated.[4] Indeed, calculations based on the car mass–fatality relationship for older cars may estimate future effects more accurately than those based on the relationship for newer cars.

All results presented in this paper are presented in terms of relative risk; they suggest that in the future, occupant risk in a small car will exceed that in a large car by a factor similar to that observed in the past. However, risks to drivers in all cars are expected to decline in the future, as they have in the past.[1,7] Factors that uniformly reduce crash risk do not affect the relationships reported here, even though they reduce the absolute number of driver fatalities. For example, if the nation were to become teetotal, traffic fatalities in essentially all categories would be reduced by approximately half.[1] As a result, the effectiveness of all occupant protection devices (and other safety measures) in reducing the absolute number of fatalities would likewise be halved, but without affecting relative risk relationships such as those reported here. Universal use of safety belts or airbags might have a small effect on the relative risk ratios reported (in addition to the main effect of reducing casualties in all types of vehicles). Although belts offer similar proportionate risk reduction in cars of all sizes, as discussed earlier, a recent finding[8] suggests a somewhat higher effectiveness in larger cars. As airbags also appear to be more effective in large cars than in small cars,[9] universal use of belts and airbags will tend to further increase the already great relative disadvantage in the smaller car. The absolute risk, rather than the relative risk, is, of course, more relevant in discussions of the cost-effectiveness of such expensive occupant protection features as increased vehicle mass or airbags.

The present study has, of necessity, focused exclusively on two-car crashes. Although about 78% of car occupants who are killed are killed in crashes other than two-car crashes,[1] the general conclusions reported here are likely to apply also to other crash types for which direct examination is not technically possible (assuming the validity of the explanation in terms of vehicle redesign).

Conclusions

When a car of a given model year crashes into another car of the same model year but 50% heavier, the driver in the lighter car is more likely than the other driver to be killed by a factor of about 3.7 to 5.1 for 1966 through 1979 model year cars, 2.6 for 1984 model year cars, and 4.1 for 1990 model year cars. These changes appear to be related to vehicle redesign. The smaller effect of car mass for the mid-1980s model years may be a result of smaller cars' containing crashworthiness improvements not yet introduced into larger cars.

In the future the relative safety disadvantage of smaller cars is expected to more closely resemble the larger effects found for pre-1979 model year cars; recent estimates based on data for all model year 1980 or later cars underestimate the extent to which driver fatality risk increases with decreasing car mass. Accordingly, future fatality increases resulting from increases in corporate average fuel economy standards will likely be greater than estimated on the basis of mid-1980 data. □

Cesarean Section and Operative Vaginal Delivery in Low-Risk Primiparous Women, Western Australia

Anne W. Read, PhD, Walter J. Prendiville, FRACOG, Vivienne P. Dawes, MBChB, and Fiona J. Stanley, MD

ABSTRACT

Objectives. A major component of the increasing trend in cesarean sections in Western Australia is the rise in emergency cesarean sections in primiparous women. The aim of this study was to identify independent risk factors (particularly those known early in pregnancy) associated with operative delivery in low-risk primiparous women.

Methods. Retrospective multivariate logistic regression analyses of antenatal and perinatal data were conducted for all low-risk primiparous women entering labor spontaneously and giving birth in Western Australia in 1987 (n = 3441).

Results. Of the subjects, 58% had a spontaneous vaginal delivery, 8% had an emergency cesarean section, and 34% had an operative vaginal delivery. The significant independent risk factors for emergency cesarean section were older maternal age, shorter maternal height, heavier infant birthweight, and long labor. The risk factors for operative vaginal delivery were older maternal age, shorter maternal height, heavier infant birthweight, epidural anesthesia, labor/delivery complications, male infant, private patient status, and being married.

Conclusions. This multivariate analysis confirms known risk factors for operative delivery in low-risk primiparous women and suggests that it may be possible to predict the likelihood of operative delivery for an individual woman by using knowledge of maternal age and height and assessment of infant birthweight. (*Am J Public Health.* 1994;84:37–42)

Introduction

Many countries have recently experienced a progressive rise in the incidence of cesarean section.[1,2] Western Australia, which witnessed an increase from 5% to 19% in the proportion of women delivered by cesarean section from 1975 to 1990, is included in this trend.[3] Cesarean sections, while usually undertaken in the interests of the offspring, may result in complications for the mother.[4] Accordingly, the wisdom of the increasing trend is in question, and efforts have been made to stabilize or reverse this situation.[5]

In a previous paper,[2] we identified the two major components of the increasing trend in Western Australia as the rise in emergency cesarean sections in primiparous women and the rise in repeated elective cesarean sections in multiparous women. Clearly, these two circumstances are related in that if a first birth is delivered by cesarean section, then subsequent births are more likely to be delivered by the same method. Therefore, it is important to investigate emergency cesarean sections in primiparas with the aim of ascertaining why they are being performed more frequently. During the 1980s, as cesarean sections increased in frequency, operative vaginal deliveries decreased.[2] Thus, we considered it important to investigate all types of operative delivery in the population.

This study was based on the total population of apparently low-risk primiparas who began labor spontaneously at term with a cephalic presentation of a singleton infant. We sought to identify, using logistic regression analysis, the significant risk factors associated with an increased chance of either operative vaginal (forceps or vacuum extraction) or cesarean section delivery in this population.

Methods

This study was carried out on existing computer files of the Western Australian Midwives' Notification of Case Attended Form 2, which are linked to the Western Australian Hospital Morbidity Data System, for the year 1987. The Midwives' Form is a statutory document completed by the midwife in attendance at each live birth and stillbirth in Western Australia, provided the infant is at least of 20 weeks gestation or 400 g birthweight.[3] There are about 25 000 births annually in Western Australia.

All primiparous women with low-risk pregnancies who gave birth in Western Australia in 1987 were selected. We defined low-risk pregnancies as follows: (1) singleton infant, (2) no recorded medical conditions or pregnancy complications, (3) vertex presentation of the infant, and (4) spontaneous commencement of labor at term (at least 37 weeks).

Women whose pregnancies fulfilled these criteria were divided into three groups according to whether they had a spontaneous vaginal, operative vaginal

This paper was accepted with revisions May 3, 1993.

(vacuum or forceps), or emergency cesarean section delivery. There were no elective cesarean sections because these women, by definition, all had spontaneous onset of labor.

Frequencies of selected demographic and perinatal characteristics for women in the three groups were coded, as shown in Table 1, in preparation for multivariate analyses. The "other" category of maternal race comprised mostly (78%) Asian women. With regard to patient classification, the universal health care system in Australia provides public hospital care by hospital doctors. In addition, people may obtain insurance that provides for treatment in private or public hospitals by doctors of their own choice. We chose a priori to investigate the variables in Table 1, together with maternal age and height, either because they have known associations with pregnancy outcome or because they are apparent early in the pregnancy and can therefore be useful predictor variables if shown to be significant. Maternal age and height can always be determined at the first antenatal visit, and we were particularly interested in these variables as potential independent risk factors for operative delivery.

Egret software (Statistics and Epidemiology Research Corporation, Seattle, Wash) was used to perform two separate multiple logistic regression analyses.[6] First, we identified the significant independent risk factors for emergency cesarean section relative to spontaneous vaginal delivery, and, second, we carried out a similar analysis for operative vaginal relative to spontaneous vaginal delivery.

A two-stage logistic regression procedure was used to fit the initial models. In the first stage, the demographic variables (maternal race, maternal area of residence, marital status, patient classification, maternal height, and maternal age) were added, followed by the perinatal variables (infant gender, infant birthweight, hours of labor, labor/delivery complications, and anesthesia/analgesia) in the second stage. At each stage, the nonsignificant variables were left in the model. The anesthesia/analgesia and labor/delivery complications variables were not used in the emergency cesarean section analysis because these items were recorded as positive for almost all women who had emergency cesarean sections (the labor/delivery complications were the indications for cesarean section). Eight women whose maternal height was not known and 44 whose patient classification was not known were excluded from these analyses (a total of 51 women).

In the models described here, the coefficient for each variable was adjusted for the effects of all other variables, however, the nonsignificant variables ($P > .05$) are not shown in the tables (with the exception of "patient classification" in Table 3). Maternal height, maternal age, and infant birthweight were factored to allow comparison with the strata at lowest risk for operative delivery according to previous literature (i.e., maternal height of 165 cm or more, maternal age of less than 20 years, and infant birthweight of less than 3000 g).[7–10]

In addition to the initial models being fitted, separate models were fitted to obtain estimated odds ratios (unadjusted for other risk factors) for emergency cesarean section and operative vaginal delivery for each maternal age/maternal height category. Further models were fitted to obtain unadjusted estimated odds ratios for each maternal age/maternal height/infant birthweight category; these values provided an estimate of the risk involved for a woman of a particular age and height according to the birthweight grouping of her infant.

Results

Of the 3641 primiparas with low-risk pregnancies who gave birth in Western Australia in 1987, 2116 (58%) had a spontaneous vaginal delivery, 1242 (34%) had an operative vaginal delivery (642 forceps, 600 vacuum), and 283 (8%) had an emergency cesarean section.

Table 1 shows the numbers and percentage distribution of women in each delivery category for selected demographic and perinatal variables. Labor or delivery complications were recorded for all but three of the women who had emergency cesarean sections. The indication for cesarean section for two of these women was long labor; the third gave birth to an infant who required intubation. Women could have had more than one complication (indication) recorded, and those recorded most frequently were cephalopelvic disproportion (56%), fetal distress (40%), and failure to progress (27%). In addition, 16% had other complications recorded, such as antepartum hemorrhage and prolapsed cord. By contrast, labor and delivery complications were recorded for only 48% of the women who had operative vaginal deliveries (3% had cephalopelvic disproportion, 20% had fetal distress, 10% failed to progress, and 21% experienced other complications). However, for some of the women in this group, the processes that led to an operative delivery would have been recorded elsewhere (e.g., a long labor would have been recorded under "hours of labor").

Women who were younger and taller were less likely to have had operative deliveries than women who were older and shorter (Table 2). Generally, within each maternal height category, the percentages of women with operative deliveries increased with increasing maternal age. Within each maternal age category, the percentages of women with emergency cesarean sections increased with decreasing height; however, this trend was not seen for operative vaginal deliveries, except in those women 35 years of age or more (Table 2).

Table 3 shows the results of the multiple logistic regression analysis in which significant independent risk factors for emergency cesarean section were compared with those for spontaneous vaginal delivery. Among the potential demographic risk factors analyzed, the most important were maternal height and maternal age, the odds ratio increasing with decreasing maternal height and increasing maternal age. All of the selected variables, with the exception of anesthesia/analgesia and labor/delivery complications, were included in this model; however, the area of residence, marital status, maternal race, and infant gender variables were not significant when all of the other variables were entered (data not shown). Although the patient classification variable was not significant in the model, it has been included in Table 3 because it represents an area of special interest with regard to the debate concerning the progressive rise in cesarean births. Private patient status was significantly associated with the outcome of emergency cesarean section until maternal age was added to the model. There were few private patients in the younger age groups; thus, any association between being a private patient and having an emergency cesarean section was due to private patients being older (data not shown). With regard to the perinatal variables, heavier infant birthweight and long labor were significant independent risk factors for emergency cesarean section.

Short maternal height was a significant risk factor for operative vaginal delivery, although there was little difference in the odds ratios for women less than 160 cm in height and those 160 to 164 cm in height. Maternal age was also a significant

predictor, the odds ratio for operative vaginal delivery increasing with each older group (Table 4). In contrast to the risks for emergency cesarean section, private patient classification and being married remained significant risk factors for operative vaginal delivery, even when the other variables were added to the model. As with the emergency cesarean section analysis, infant birthweight was a significant independent risk factor for operative vaginal delivery. Both labor/delivery complications and anesthesia/analgesia were significant independent risk factors for operative vaginal delivery when all other variables were included in the model, and epidural anesthesia was the most significant risk factor of all those included in the model (Table 4).

Table 5 shows that the estimated odds ratios increased as maternal age increased and maternal height decreased; thus, women 35 years of age or more and less than 160 cm tall were at the highest risk. In Table 6, the estimated odds ratios increased with maternal age within each height category but did not vary greatly between the height groups.

Estimated odds ratios for each maternal age/maternal height/infant birthweight category (unadjusted for other factors) were also obtained for both emergency cesarean section and operative vaginal delivery. The complete results from this analysis are not shown because there were small numbers in some of the cells. For example, in Table 5, there were fewer than five women in three of the categories, and these women would have been subdivided further into the three birthweight categories. However, with larger numbers of deliveries available for analysis, it would be useful to examine the combined risk for operative delivery according to birthweight of the infant as well as age and height of the mother. As an example, in one of our categories with a satisfactory number of women for analysis (those 25 to 29 years of age and 160 to 164 cm tall), the estimated odds ratios for emergency cesarean section relative to spontaneous vaginal delivery were 7.2 if the infant's birthweight was less than 3000 g, 14.9 if birthweight was 3000 through 3499 g, and 34.0 if birthweight was 3500 g or more. The estimated odds ratios for operative vaginal relative to spontaneous vaginal delivery for women in the same age/height category were 3.3 if the infant's birthweight was less than 3000 g, 5.4 if birthweight was 3000 through 3499 g, and 9.4 if birthweight was 3500 g or more.

Discussion

Most studies of obstetric databases have been descriptive. More recently, multivariate techniques have been described in order to control for confounding factors so that significant independent risk factors for obstetric outcomes may be ascertained and quantified.[11] However, there have been few population-based studies, such as ours (which included all low-risk primiparas giving birth in Western Australia in 1987), that use multivariate analyses and include factors such as maternal age and height and infant birthweight.

The operative delivery rates in this low-risk group of women were found to be high. While similar proportions may be found in other units and populations of the Western world, lower operative delivery rates in low-risk primiparas have been reported by individual hospitals in Ireland (cesarean section rate = 6%, operative vaginal rate = 19%) and the United States (cesarean section rate = 12%, operative vaginal rate = 27%).[12] However, a study of a comparable Australian population

[c]Odds ratios relative to birthweight of less than 3000 g.

giving birth in Sydney teaching hospitals found a cesarean section rate of 5% and a forceps delivery rate of 43%.[13] A degree of caution is needed when comparing different publications referring to low-risk populations, even when relatively strict inclusion criteria, such as those we have described here, are used. For example, including only primiparas in spontaneous labor excludes those whose labors are induced; indications for induction of labor vary considerably from one hospital to another and will affect the population "allowed" to proceed to spontaneous labor.

In our multivariate model, private patients were not significantly more likely to have an emergency cesarean section than were public patients, but they were more likely to have an operative vaginal delivery. Cary[14] studied 24- to 25-year-old low-risk primiparas in Queensland, Australia, and found more cesarean section (15% vs 10%) and operative vaginal deliveries (32% vs 21%) in private than public patients. However, Cary did not control for maternal height, infant birthweight, or other potential confounding factors. Hewson et al.[13] studied a similar group of low-risk primiparas in Sydney teaching hospitals and found no significant differences between private and public patients with regard to mode of delivery. In a study of low-risk women in the United States, Haynes de Regt et al.[15] found significantly higher proportions of cesarean sections in private than public patients after allowing for age and parity in one analysis and infant birthweight category in another. In a low-risk population in the United Kingdom, Klein et al.[16] found a significantly higher proportion of forceps deliveries in private than public patients, but there was no significant difference in these two groups with respect to cesarean sections. This was a result similar to that of our study, but Klein et al. did not control for potential confounding factors.

The strong independent effect of maternal age was an important confounding factor when investigating the public/private patient dichotomy with regard to emergency cesarean section, and maternal age may have more influence in primiparas than multiparas.[2,9] Although primiparas of advanced maternal age (e.g., over 35 years) have long been thought to be more likely to have an operative delivery,[7] it is apparent from these analyses that primiparous women 20 to 30 years of age are also more likely to have such an outcome than are primiparas less than 20 years old. The precise explanation for this age-related trend remains uncertain.

Yudkin and Redman[17] found dystocia to occur more frequently in older primiparas than in teenagers. It may be that teenagers are physically more fit for the processes of labor and delivery than are older women. A recent Israeli study using multivariate analysis found a decrease in the risk of cesarean section for teenagers and an increase for women 37 years of age or more, the authors noting that the management of labor may be different in teenagers than in older women.[11] Also, Gordon et al.[18] found that maternal age per se may influence an accoucheur's decision regarding method of delivery, and this may have been the case in our population.

Short maternal height predisposes women to operative delivery.[7,8] Our study has documented an increased chance of operative delivery for low-risk primiparas of both short (less than 160 cm) and medium stature (160 to 164 cm) relative to taller women. Moreover, these increases were independent of other potential and real risk factors such as maternal age, race, and marital status and infant birth-

weight. For primiparas, the increasing trend in emergency cesarean section rates with decreasing maternal height has also been shown by Yudkin and Redman.[17]

As illustrated in Tables 5 and 6, maternal age and height can be used together to provide an indication of the increased risk for operative delivery in this population as maternal age increases and maternal height decreases. At every age, women of medium height were twice as likely as taller women to have a cesarean section, and women of short stature were four times more likely to undergo the procedure. At every height, the likelihood of a cesarean section was 10 times greater for women 35 years of age or more than for teenagers. In contrast, height was not as important for operative vaginal delivery, but age was strongly related.

Turner et al.,[10] when investigating nulliparas, found that heavier infant birthweight was a significant risk factor for both cesarean section and forceps delivery for dystocia. In our study, the relationship between birthweight and operative delivery persisted when adjusting for confounding factors such as maternal age and height and infant gender.

Because the timing of epidural anesthesia during the course of labor was not available in our database, we did not investigate this procedure with regard to cesarean section delivery. However, because of the likelihood that most epidurals would have been instituted in early labor and the importance of epidural anesthesia in the progress of labor and type of delivery,[19–21] we included it in our regression models for operative vaginal delivery. Here we found it to be the most important independent risk factor, the relative odds being approximately three times greater than those for labor and delivery complications. Several studies,[13,19,20] including randomized controlled trials,[21] have shown that epidural anesthesia is likely to lead to longer labor and operative delivery.

Our analysis has shown the value of using multivariate models to identify risk factors for operative delivery, particularly when comparing outcomes for different hospitals. Investigations of modifiable risk factors and evaluations of different forms of management of labor should use similar techniques. □

Physicians' Recommendations for Mammography: Do Tailored Messages Make a Difference?

Celette Sugg Skinner, PhD, Victor J. Strecher, PhD, MPH, and Harm Hospers, MA

ABSTRACT

Objectives. **Message tailoring, based on individual needs and circumstances, is commonly used to enhance face-to-face patient counseling. Only recently has individual tailoring become feasible for printed messages. This study sought to determine whether printed tailored recommendations addressing women's specific screening and risk status and perceptions about breast cancer and mammography are more effective than standardized printed recommendations.**

Methods. **Computer-assisted telephone interviews were conducted with 435 women, aged 40 to 65 years, who had visited family practice groups within the previous 2 years. Subjects were randomly allocated to receive individually tailored or standardized mammography recommendation letters mailed from physicians to patients' homes. Follow-up interviews were conducted 8 months later.**

Results. **Tailored letter recipients were more likely to remember and to have read more of their letters than standardized version recipients. After controlling for baseline status, tailored letter receipt was associated with more favorable follow-up mammography status for women with incomes below $26 000 and for Black women.**

Conclusions. **Tailored messages are a more effective medium for physicians' mammography recommendations; tailoring may be especially important for women of low socioeconomic status. (*Am J Public Health.* 1994;84:43-49)**

Introduction

Breast cancer affects about 1 in 10 women and is one of the three most frequent causes of death among women in the United States.[1] Regular mammography screening has demonstrated effectiveness in reducing breast cancer mortality.[2-11] Although nearly all health organizations recommend mammography screening[12-19] and rates have been increasing,[20,21] most women are still not screened regularly.[21,22] Women of lower socioeconomic status are least likely to have regular mammograms.[20,23-27]

Most identified factors influencing women's mammography decisions can be classified as variables from the Health Belief Model,[28,29] which purports that perceptions about benefits and barriers associated with a health behavior, perceived personal risk and severity of the relevant health threat, and various cues to action work together to influence a person's likelihood of taking a preventive health action.

It is also likely that with regard to mammography as well as other health-related behaviors,[30-32] individuals move through a series of motivational and behavioral stages in which the behavior is not considered ("precontemplation"), the behavior is contemplated but not yet acted upon ("contemplation"), an initial behavior change is made ("action"), and the behavior is maintained over time ("maintenance") or the person relapses from action or maintenance to a previous stage. Research with other behaviors has found utility in considering health-related behavior changes in these categories[32-36] and has found a broad range of psychosocial determinants predicting movement from one stage to another.

Among factors correlated with mammography status are women's beliefs about breast cancer and the ability of mammography to detect early breast cancer[23,25,37-40] and perceived barriers to mammography screening, such as cost, concern about radiation exposure, or fear of finding cancer.[25-27,39-43] A physician's recommendation, however, has emerged as an even stronger predictor of mammography than women's perceptions about the procedure.[21,26,39,42-44]

Therefore, it is likely that mammography recommendations in the form of letters mailed from physicians to patients' homes would have an impact on women's propensity to be screened. We used computer technology to assemble individualized letters tailored according to women's responses in baseline interviews. Message adaptation, based on individual needs and circumstances, is commonly used to enhance the effectiveness of face-to-face patient counseling,[45,46] but only recently has such individual tailoring become feasible for printed messages. We sought to determine whether printed tailored recommendations addressing women's specific screening and risk status and their perceptions about breast cancer and mammog-

At the time of the study, Celette Sugg Skinner and Victor J. Strecher were with the Department of Health Behavior and Health Education, School of Public Health, University of North Carolina at Chapel Hill. Harm Hospers is with the Department of Health Education, University of Limburg, Maastricht, the Netherlands.

This paper was accepted June 3, 1993.

Editor's Note. See related editorials by Shapiro (p 10), and Zapka (p 12) in this issue.

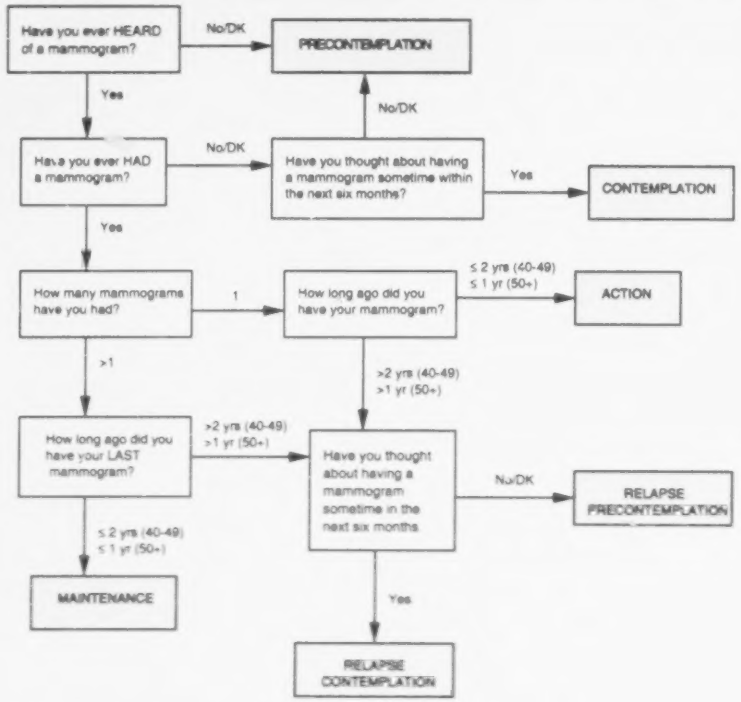

FIGURE 1—Mammography stage diagram.

raphy are more effective than standardized printed recommendations.

Methods

The eligible study population was a random sample of women aged 40 through 65 years who had visited one of two North Carolina family practice groups within the previous 2 years, had telephones, and had never been diagnosed with breast cancer. Study subjects were interviewed at baseline and randomly allocated to receive individually tailored or standardized letters. Whereas the general letter delivered a standardized message to all recipients, tailored letters addressed individual beliefs and barriers associated with mammography, as well as breast cancer risk factors and screening status. Follow-up interviews 8 months later reassessed the subjects' screening status and perceptions and measured letter recall and readership. Data were collected via computer-assisted telephone interviews.

The eligible study population consisted of 899 patients from both practices. Fifty-eight women (6%) refused to be interviewed, 10 interviews were terminated (1%), and 334 (37%) patients were never reached after an average of 7 attempts over 10 days. Two hundred patients from practice A and 297 from practice B were enrolled. Samples from the two practices were similar in racial and age distributions but differed somewhat in income and education levels. To minimize effects of differences, half of the subjects from each practice were randomly allocated to receive tailored versus standardized letters.

Baseline interviews asked the women about their mammography stage, their knowledge and beliefs about breast cancer and mammography, their objective and perceived risk status, and barriers to screening. Descriptions of measures follow.

Stage Determination (Likelihood of Taking Action)

We adapted a stage model of smoking cessation developed by Prochaska and DiClemente.[30-32] On the basis of their responses to several questions, women were classified as precontemplators, contemplators, actors, or maintainers. Figure 1 depicts the measures by which stages were defined.

The respondents were asked whether they had heard of mammograms and, if so, whether they had had one or more. All respondents who had heard of mammography but had not yet been screened were asked whether they had thought about being screened in the 6 months immediately following the interview. Respondents who had never heard of mammography or who had not thought about having a mammogram in the following 6 months were *precontemplators*. Those who had thought about having mammograms in the following 6 months were *contemplators*.

Following study physicians' recommendations and the American Cancer Society guidelines for frequency of mammography screening, women aged 50 years and older were considered due for repeat mammograms if their last mammograms had been more than a year ago and women aged 40 through 49 were considered due for rescreening if more than 2 years had passed since their last mammograms. Those who had not thought about having another mammogram in the following 6 months were *relapse precontemplators*, whereas those who had thought of being rescreened in the following 6 months were *relapse contemplators*. Those not yet due for rescreening were *actors* (had had one mammogram) or *maintainers* (had had two or more mammograms).

Beliefs about Benefits and Barriers Associated with Mammography

The interview assessed the subjects' beliefs about the ability of mammograms to detect early breast cancers and about the likelihood of curing breast cancers detected at an early stage. Responses were measured on 5-point scales.

Perceived barriers were elicited by the open-ended question "What would keep you from having a mammogram in the next 6 months?" Additionally, closed-ended questions assessed the extent to which respondents would be bothered by cost, discomfort, fear of finding cancer, and concern about radiation.

The Mammography Letters

A library of texts and graphics files was created to address varying beliefs, mammography stages, risk factors, and barriers. Messages were pretested in physicians' waiting rooms among patients not included in the sample. The brief message texts were written in a simple, popular style and could occur in any possible text combination. Desktop publishing techniques were used to enter message texts in predefined locations in the letter layout. Specifically, interview data from women in the experimental group were transferred from an SAS[47] data set to an ASCII file that delineated which text version each woman should receive. Data in each woman's ASCII file were then read by a Microsoft

Word[48] program that inserted message texts appropriate for her. A combination of messages was created to specifically address each woman's beliefs about mammography and breast cancer, mammography stage, risk status, and perceived barriers. More than 391 000 different tailored letters were possible. Every woman's letter was different from every other woman's unless the women had given identical responses in the baseline interview.

Five months after the baseline interview, the subjects received tailored or standardized letters according to the previous random assignment. Each letter was accompanied by a cover letter on a physician's letterhead with a digitized signature. Envelopes bore physicians' logos, address labels, and commemorative stamps.

The standardized message typifying usual care communications was an adaptation of the 1987 surgeon general's mammography letter.[49] To minimize differences in appearance, standardized and tailored letters were printed in the same typeface on the same stationery and were similar in length. Both had a picture of a woman, but tailored letters had digitized photographs tailored by race, accompanied by captions tailored by stage.

Whereas the standardized letters addressed a variety of factors that *might* be relevant to recipients, the tailored letters addressed only those that, according to the baseline interviews, *were* relevant to the recipients. For instance, tailored messages reported the risk factor of age only for women who were older than 50 and the risk factor of family history only for women who had a relative with breast cancer.

The tailored letters contained individual-specific information but were framed to sound as though they were written for general audiences. They were written as reports of findings from the telephone interviews in which all letter recipients had participated. For example, instead of "Since you, personally, have never even thought about having a mammogram . . . ," the messages read, "Many women surveyed have never even thought about having a mammogram. . . ."

Follow-Up Interviews

Second telephone interviews—conducted 3 months after the letters were mailed and 8 months after the baseline interviews—measured letter recall and readership and reassessed respondents' stage, perceived barriers, knowledge, and beliefs.

Recall of letter receipt was assessed in both unaided and aided format. The unaided question asked whether respondents had recently received any health information in the mail from the study physicians. If respondents did not remember or were unsure, they were prompted with a reminder about the letters and then asked again. For those who remembered the letters, readership was assessed on a 4-point scale ranging from "Read all of the information" to "Didn't read any of it."

Eight study subjects whose mammography recommendation letters had been returned to sender and for whom no new addresses could be found were dropped from the sample between baseline and follow-up. Of the remaining 489 subjects interviewed at baseline, 435 (89%) were reinterviewed at follow-up (170 women from practice A and 265 from practice B). Twenty-four subjects (5%) refused the second interview, 26 (5%) were never reached after an average of 7 attempts over 10 days, and 4 (1%) interviews were terminated.

Analyses

Assignment to experimental (tailored) or control (standardized) group was an independent variable for all analyses. Follow-up data were used to assess letter recall and readership. Both baseline and follow-up data were used to assess behavioral changes. Rather than conducting separate analyses for women who did and did not recall their letters or for women who did and did not read any of the information, in analyses for the full sample we controlled for letter recall and readership in assessing changes in mammography screening stage. Multivariate analyses were used to examine the main effects of the intervention on changes in mammography stage and on having a mammogram. Effects of the intervention were also examined within demographic groups (race, income, education, and age) for which mammography stage differed significantly at baseline. These demographic variables were entered into multivariate analysis models as interaction terms.

Results

The sample's demographic make-up was as follows: 53% were in their 40s, 84% were White (the remaining 16% were Black), and 68% were employed. Ten percent had not finished high school, 47% had at least attended college, and 16% had done graduate work. Forty percent had household incomes of $36 000 or more, 17% had incomes of $26 000 to $36 000, and 43% had incomes below $26 000. Bivariate analyses revealed no significant differences in any demographic characteristics, in family history of breast cancer, or in baseline mammography stage between experimental and control groups.

Recall and Readership

Most women (63%) remembered receiving their letters; 54% remembered without being prompted and an additional 9% remembered after a reminder. Only 17% of the women who remembered receiving a letter did not read any of the information. Whereas 36% of those who remembered receiving a letter read only some of the content, 23% read most and 24% read all of it. Among the 226 women who read at least some of the content, 30% said the information was very interesting and 59% found it at least somewhat interesting.

Bivariate analysis revealed that women who received tailored letters were more likely to remember them than were standardized letter recipients ($P < .05$). Further, among the 272 women who remembered the letters, tailored letter recipients were significantly more likely to read more of the content ($P < .01$). More than half (53%) of the tailored letter recipients who recalled the letter reported reading all or most of it, compared with 40% of standardized letter recipients.

Although women with higher educational levels were more likely to remember receiving the letters ($P < .01$), among those who read at least some of their letters, more well-educated women were less likely to report interest in the content ($P < .01$). Also, White women were more likely to remember receiving the letters ($P < .05$), but among women who remembered and read at least some of the letters, Black women reported more interest in the content ($P < .01$). A baseline perception of being at elevated risk for breast cancer was significantly related to reading more of the letter ($P < .01$). However, tests for interactions revealed no significant effects of these correlates and letter type on recall, readership, or interest.

Mammography Stage Movement

The study categorized respondents into mammography stages. Precontemplators, whether they had never had a mammogram or were due for rescreening, needed mammograms but had not thought about having them in the following 6

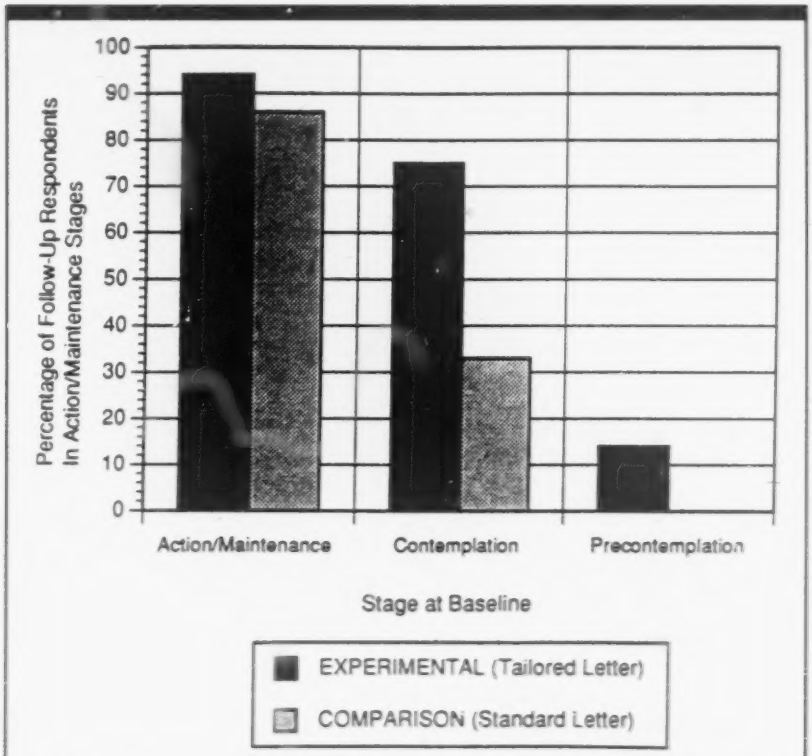

FIGURE 2—Movement toward action/maintenance stage of mammography use (Black women, n = 70).

months. Contemplators, also due for mammography, had thought about having mammograms at some time in the following 6 months. Actors and maintainers (grouped together for these analyses) were not due for repeat screening within the next 6 months. Within these stages, the possibility of forward and backward movement is apparent. The goal of the intervention was to move women into the action/maintenance category and keep them there by preventing relapse.

At baseline, 64% of all women in the sample had had mammograms within the recommended interval and were not due for rescreening. Women were more likely to have had recent mammograms at baseline if they were White ($P < .05$), had higher incomes ($P < .001$), and had higher education levels ($P < .01$). Thirty-five percent of White women, compared with 43% of Black women, were due for mammography screening at baseline. Only 28% of women with incomes over $26 000, compared with 47% of women with lower incomes, were due for screening at baseline. Forty-three percent of women who did not attend college, compared with 29% of those who did, were due for mammography at baseline. Age was associated with screening; women in their 40s were less likely than women aged 50 years and older to be due for a mammogram ($P < .001$).

The rate of women who had had recent mammograms increased from 64% at baseline to 68% at follow-up. Of the 152 women who were due at baseline, 37% had had mammograms by follow-up. Among those due for screening at baseline, more of the tailored letter recipients (44%) than the standardized letter recipients (31%) had had mammograms by follow-up. However, the difference was not statistically significant ($P = .16$).

A woman could progress from precontemplation (not thinking about having a mammogram in the next 6 months) to contemplation (thinking about having a mammogram in the next 6 months) without actually having a mammogram. Conversely, she could regress from contemplation to precontemplation. Actors and maintainers could relapse to precontemplation or contemplation stages if, by the follow-up interview, they had become overdue for rescreening. The majority of subjects (71%) did not change stage between baseline and follow-up (14% advanced one stage, 4% advanced two stages, 8% moved one stage back, and 3% regressed by two stages). There were no significant main effects for stage movement by letter type.

Analyses were conducted to determine whether the intervention had a significant effect on mammography within demographic subgroups. Letter type was not differentially associated with stage movement for different education or age groups. For Black and low-income women, however, receipt of tailored letters, compared with standardized letters, influenced mammography stage improvement and mammography screening rates. After controlling for stage at baseline, significant race × intervention ($P < .05$) and income × intervention ($P < .01$) interactions were found.

To determine the nature of the interaction effects, we ran four separate models for lower-income, higher-income, Black, and White women. Letter type was significantly associated with stage movement among Black women ($P < .05$) but not among White women ($P = .47$). Twenty-seven percent of Black women who received tailored letters, compared with 8% in the standardized letter group, exhibited forward stage movement at follow-up. Further, letter type was significantly associated with stage movement among women with incomes below $26 000 ($P < .01$) but not among higher-income women ($P = .30$). In the lower-income group, more tailored letter recipients moved forward (28% vs 17% of standardized letter recipients) and fewer moved backward (8% vs 15% of standardized letter recipients).

Figure 2 depicts percentages of Black women in the action/maintenance stage at follow-up, delineated by baseline stage and letter type. Figure 3 depicts corresponding breakdowns for women with household incomes below $26 000. For both Black and low-income women, baseline precontemplators and contemplators were more likely to have had mammograms at follow-up if they had received tailored rather than standardized letters. Similarly, among both groups, baseline action/maintainers who received tailored letters were less likely to have relapsed than were standardized letter recipients.

Discussion

In this study we sought to determine whether printed physicians' recommendations for mammography would be more effective if they were tailored to individual women's specific perceptions about mammography and breast cancer, their breast cancer risk factors, and their mammo-

graphy screening status. The results indicate that tailored letters were a more effective medium for delivering the message: tailored letters were more likely to be remembered and, among women who remembered the letters, were more thoroughly read.

There are several explanations for why the tailored letters were better remembered and more thoroughly read. Although the tailored and standardized letters were designed to be equally attractive, tailored letters may have had a greater chance of capturing attention at first glance because of their tailored pictures, captions, and headlines. Tailoring allowed for a specificity in the letters' eye-catching elements that was not possible in the standardized version. For example, the caption for relapse precontemplators' letters read, "I've had a mammogram but I never even thought about having another one."

Had the standardized letter contained such specificity, some of its elements would have been irrelevant, and possibly off-putting, for a portion of its recipients. Further, the specificity of content allowed in the tailored letter kept recipients from reading information that did not apply to them. In other words, tailoring enhanced relevance. For instance, because only risk factors relevant to the recipient were printed, a woman could not read a list of three risk factors and feel consoled by the fact that only one applied to her. Tailored letters may have simply received enhanced attention, which in turn led to forward stage movement. In the context of the Health Belief Model,[29] they may have been more effective cues to action.

Most women (64%) entered the study with an up-to-date mammography status. This rate increased to 68% by follow-up. Although more women in the tailored than the standardized group had had recent mammograms at follow-up, the difference did not achieve statistical significance. Among Black and low-income women, whose recent screening levels were lower at baseline, tailored letter recipients were more likely than standardized letter recipients to move toward mammography. In addition, those who received the tailored letters were less likely than standardized letter recipients to move backward or relapse.

This study has several limitations. For instance, its generalizability is limited by the exclusion of women without telephones. In addition, there is a possibility that women who were never reached were different from those who were contacted.

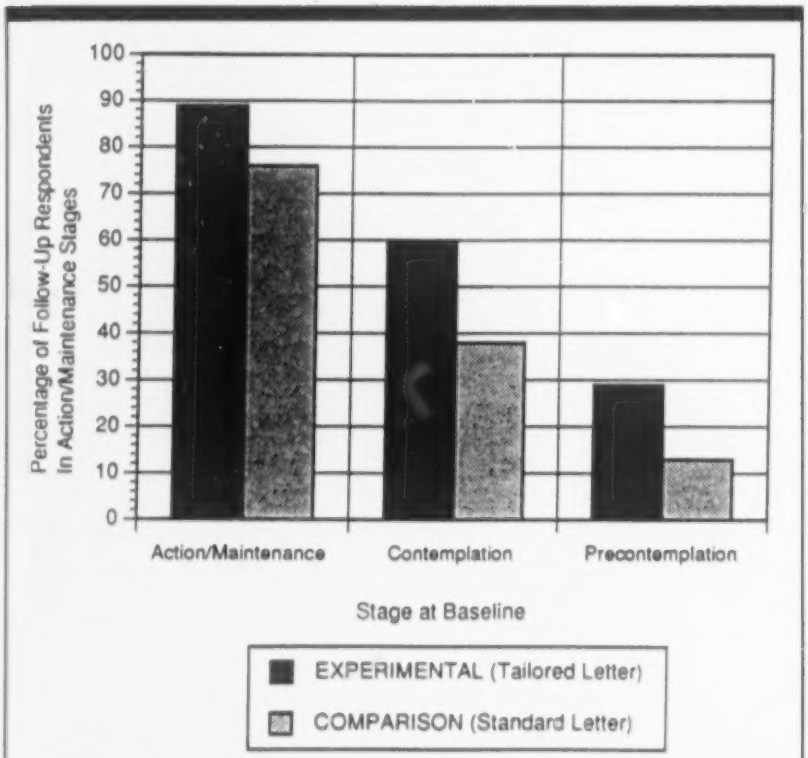

FIGURE 3—Movement toward action/maintenance stage of mammography use (women with household income < $26 000; n = 171).

Women not reached may have been out of town during the calling period, may have been generally busier and at home less often than those who were reached, or may have screened their calls via answering machines and chosen not to answer. It seems unlikely, however, that any differences between those who were and those who were not reached would be associated with the effect of receiving a tailored or standardized letter.

For the sample as a whole, higher-than-expected mammography rates at baseline resulted in limited statistical power to detect postintervention differences between tailored and standardized groups. Among subgroups, it is unclear whether there were aspects of the tailored letters that were particularly effective for Black and low-income women or whether there was a ceiling effect for White and higher-income women because their percentage of possible change was limited by elevated baseline rates. Either way, the most important finding of this study is its demonstration that tailored physicians' recommendations effected health behavior change among hard-to-reach populations. Minority and low-income women have historically had lower mammography rates than White women and those with higher incomes, and they remain underscreened although screening rates continue to rise in the general population. In fact, the mammography gap between higher-income White women and lower-income minorities may be widening.[20] Therefore, an intervention found to be effective among lower-income and minority groups is especially timely and important.

It is somewhat surprising that the effect of the tailored letters was significant for Black and low-income women, because print media are not generally expected to be as effective among lower socioeconomic groups as among higher socioeconomic groups. To combat this disadvantage, letters were targeted toward lower reading levels by means of simple vocabulary and clear, one-sided arguments. In effect, the intervention delivered a low-socioeconomic-status message through a high-socioeconomic-status channel. This may explain why Black and low-income women were among the least likely to have read their letters but, for women who read at least part of the letters, the most likely to report interest in the content.

The effect of tailored recommendations cannot, in this study, be disentangled from the personal nature of letters coming

from physicians to women's homes. It is difficult to determine whether the advantage in tailoring would also be present for messages delivered via other media. Women of low socioeconomic status may have been persuaded more by the fact that their physicians sent them a letter than they would have been by an even easier-to-understand presentation in the physician's office.

The next phase in tailoring research should compare different types and amounts of tailoring and different media channels. For instance, interactive computer programs employing graphics, sound, and touch screens could deliver messages to low-literacy women who are not able to read letters. Such messages could allow for additional tailoring. Not only could more content be tailored, but presentation factors such as type size, graphics, reading level, and sophistication of arguments or message framing could be manipulated.

Future research should also explore whether effects of tailored physicians' recommendations are similar for patients in public health clinics, where physician–patient relationships may be very different from those in family practice settings. Even if tailored recommendations are found to be more effective in moving women toward mammography, they may not provide women with the skills needed to negotiate the medical system and actually obtain mammograms. □

The Collaborative Registry of Smoking Cessation Trials Issues a Request for Help

Over the past 10 years there has been a significant increase in the number of randomized controlled trials that compare the effectiveness of different interventions in smoking cessation. Recently, a number of researchers have been approached to obtain information about current trials for a prospective registry of planned or ongoing trials in the area of smoking cessation. Although the initial response has been encouraging, it is possible that some people have been inadvertently missed. To ensure that a registration form is completed by the principal investigator for all relevant trials, we are seeking the help of all researchers.

To be eligible for inclusion in the registry, a trial must be unpublished and include at least two groups; allocation to the groups must be by either a random or quasi-random method (e.g., alternation, year of birth, etc.); and the trial must be related to an aspect of smoking cessation. Trials examining abstinence rates, relapse prevention, withdrawal symptoms, training or encouraging health professionals in smoking cessation techniques, or any aspect of smoking cessation research are all eligible for inclusion. If you are in doubt as to whether a trial is suitable for inclusion, we suggest you still complete a registration form.

Once the register has been assembled, a copy will be distributed to all contributors, as well as published in summary form on an annual or biannual basis. The registry will not collect any trial result data or participant information, although the existence of such a register may facilitate the establishment of collaborative groups who wish to undertake more detailed systematic reviews, similar to those undertaken in other fields.

Trial registration forms are available on request from The Collaborative Registry of Smoking Cessation Trials, General Practice Research Group, Gibson Building, Radcliffe Infirmary, Oxford OX2 6HE, United Kingdom; tel +44-865-319 124; fax +44-865-310 545.

The coordinators would also appreciate being informed of any completed but unpublished smoking cessation trials. No special form is provided for this purpose; however, any information that researchers can provide will assist in updating our current register of completed trials and ensure its comprehensiveness.

Mammography Screening: How Important Is Cost as a Barrier to Use?

Nicole Urban, ScD, Garnet L. Anderson, PhD, and Susan Peacock, BA

ABSTRACT

Objectives. Recent legislation will improve insurance coverage for screening mammography and effectively lower its cost to many women. Although cost has been cited as a barrier to use, evidence of the magnitude of its effect on use is limited.

Methods. Mammography use in the past 2 years among women aged 50 to 75 residing in four suburban or rural counties in Washington State was estimated from 1989 survey data. Logistic regression analysis was used to estimate the odds ratio of mammography use as a function of economic and other variables. Within a residential area, averages were used to measure the market price of mammography and the time cost to obtain a mammogram.

Results. Use was lower among women who faced a higher net price or who preferred to obtain a mammogram during weekend or evening hours and higher among women with higher incomes. Visiting no doctor regularly and smoking were predictors of failure to use mammography.

Conclusion. The effects of economic variables on mammography use are important and stable across subsets of the population, but they are modest in size. (*Am J Public Health.* 1994;84:50–55)

Introduction

The burden of breast cancer in the United States is great and is not likely to decrease in the near future.[1] Although one out of nine US women can expect to be diagnosed with breast cancer during her lifetime, and regular screening by mammography among women aged 50 or older has been shown to reduce breast cancer mortality by 30% or more,[2,3] surveys done between 1988 and 1989 suggest that fewer than 42% of US women aged 50–75 have had mammography in the past year and that over 25% of women aged 50–75 have never had a mammogram.[4]

The reasons most frequently cited by women for never having had mammography are that they do not have any problems with their breasts, and that their doctors never recommended it.[4–10] A recent study of use of mammography by primary-care physicians found cost and lack of insurance coverage to be major deterrents to use.[10] In studies of women's use of mammography in which cost has been measured, cost has been identified as a factor influencing use,[5,8] and the role of insurance has been found to be important.[5,9]

If cost is a significant barrier, mammography use can be expected to increase in the next decade because recent legislation in many states mandates that screening mammography be included among covered services in private health insurance policies,[11] and many of the remaining states have passed or are considering legislation mandating coverage of screening mammography by insurers. Moreover, effective January 1, 1991, biennial screening mammography has been reimbursable by Medicare. Until then, Medicare reimbursed 80% of reasonable and customary charges for diagnostic mammography once the deductible was met, but benefits for screening mammography were not provided.

This paper examines the role of economic variables, including insurance coverage, in the use of mammography among women aged 50–75 in four counties in Washington State before implementation of legislation that improved insurance coverage. Data are presented describing the perceptions of women in 1989 regarding their insurance coverage for screening mammograms and the influence of cost and insurance coverage on use. The bivariate relationships among recent mammography use and insurance coverage, mammography price, and income are reported for women aged 50 to 64 and for women aged 65 to 75.

An economic behavioral model, the theory of demand, suggests that the price of mammography is a key variable. Total price to the consumer is the net money price plus the time cost. The net money price is equal to the price charged for the mammogram less the amount paid by insurance, or the price charged multiplied by the coinsurance rate. The time cost is the total time required to obtain a mammogram. Other things being equal, as the net price of a screening mammogram falls, regular screening mammography will be used by more women. The theory of demand suggests as well that (1) use will rise with income; (2) use will rise with a fall in the time cost; (3) as the net money price falls, sensitivity to time cost will rise; and (4) price sensitivity will be greater among

low-income women for whom price represents a larger proportion of disposable income. The results of multivariate analyses to test these hypotheses are reported.

Methods

Data and Variable Definitions

Data on mammography use were obtained from a telephone survey conducted in spring 1989 of women aged 50–75 residing in four communities. The communities were selected on the basis of their comparability with respect to size, sociodemographics, and proximity to an urban area from among all the suburban and rural counties in Washington State with at least 10 000 women aged 50 and above. To be eligible for the survey, women had to be between the ages of 50 and 75, had to have lived in their county of residence for 2 or more years, and had to have no history of breast cancer. Approximately 97% of the target population had telephones; of those without telephones, many would have been ineligible for the survey due to lack of 2-year residence in the community. A total of 1538 women were interviewed through a random-digit dial survey technique that samples numbers proportional to size (for residential lines) within a dialing prefix, producing a self-weighted stratified sample for the geographical areas.[12] The response rate to the survey was 72%, calculated as the number of completed surveys divided by the estimated number of eligible women sampled, which was quite good relative to the response rates reported in similar surveys.[4] The denominator included an estimate of the number of eligible women in households at telephone numbers that were sampled but were not reached (n = 192), as well as all eligible women reached (n = 1937). To avoid selection bias, the introduction to the survey described it as relating to the health of women rather than to mammography specifically. The questions used to elicit relevant information from women respondents are available from the authors on request.

The use of mammography was defined as one or more mammographic studies in the past 2 years, based on the woman's self-report. Validation was not undertaken because validity of self-reported mammography use has been found to be very good in other studies.[13] Although interest was primarily in screening mammography, no attempt was made to distinguish between screening and diagnostic mammograms because the distinction between them is insufficiently clear among physicians to be recognized reliably by women.[14] Of women who had ever had a mammogram, 82.4% reported that their last mammogram was for a routine check-up rather than for a current or previous breast problem. We are therefore confident that the majority of mammograms were for screening purposes.

Specification and Estimation of the Multivariate Models

Variables were selected for inclusion in the analytic model on the basis of microeconomic theory and the health economics literature. A single-equation model was specified that related use of mammography in the past 2 years to (1) economic variables and (2) other determinants of demand that reflect the value that women place on mammography as a contributor to their health.[15] Economic variables included in the model were the out-of-pocket cost to the woman of a screening mammogram (the net money price), the cost in time that is incurred to obtain the mammogram, whether or not weekdays are inconvenient for obtaining the mammogram, and household income.

The net money price was defined as the total charge for the mammography multiplied by the proportion of that charge paid by the woman rather than by her insurance company. For women with insurance that pays all of the cost of mammography, the net price is zero. The time cost was defined as the total time a woman would need to obtain the mammogram, including travel time to the facility, waiting time, and the time required to receive services. Measurements of the net money price and the time cost are described below. Inconvenience was measured as a woman's preference for evenings or weekends over weekdays to obtain the mammogram. Income was measured as reported total household income.

Theory suggests that demand is a function of the value of the good or service to the consumer, as well as a function of prices and income. The value of breast cancer screening to a woman was assumed to depend on her risk of breast cancer, measured by her age and family history of breast cancer; her valuation of her breast health, measured by her monthly practice of breast self-examination; and her valuation of her health more generally, which for lack of a better indicator was measured by her current smoking habits. Screening mammography can be viewed as an investment in health. Because microeconomic theory suggests that consumers with more education can be expected to invest more in their health,[15] years of education completed were also included in the model.

Because a woman may depend on her physician to assess the value of screening mammography for her,[16] a set of dummy variables indicating the type(s) of physician(s) she visits regularly were constructed. Based on bivariate analyses, these variables were reduced to two: an indicator that the woman regularly visits a gynecologist and an indicator that she does not visit any provider regularly. Because the probability of referral for mammography by a physician may increase with exposure to physicians, the average number of annual visits to providers whom the woman sees regularly was included as well.

Logistic regression analysis was used to estimate the model from the survey data obtained from the women. Of the 1538 women surveyed, there were 1528 usable interviews, of which 1377 had sufficiently complete data to be included in the demand analyses. The dependent variable was set equal to 1 if the woman reported having a mammogram within the last 2 years and set equal to 0 otherwise. The statistical software package EGRET[17] was used to estimate the model. Dummy variables were included for three of the four counties to account for county effects and any intraclass correlation among women in the same county.

An equation was also estimated in which the economic variables were omitted, in order to test their importance as a group; and two additional equations were estimated to test the interaction effects of economic variables with the economic conditions of the women. First, interaction effects were estimated for women with insurance covering more than half of the cost of screening mammography, which permitted a test of the hypothesis that sensitivity to the time cost is greater among well-insured women. Second, interaction effects were estimated for women with household incomes above $15 000, which yielded a test of the specific hypothesis that sensitivity to the money price is greater among low-income women.

Estimation Issues in the Multivariate Analyses

Missing values for economic variables were an important source of potential selection bias in these analyses. Among the 1528 usable interviews, the prevalence of missing values for reported

price, reported insurance coverage, reported time cost, and income were 19.4%, 26.5%, 9.7%, and 16.1%, respectively. Moreover, missingness for three of these economic variables was related to mammography use. Simple chi-square tests of independence between the variable indicating whether a woman had a mammogram in the last 2 years and the variables indicating whether or not she reported money price, insurance coverage, and time cost were highly significant ($P < .001$). Missingness for income was not related to mammography use.

Another potential source of bias was a possible correlation of reported price (in money, time, or both) and insurance coverage with the error term of the demand equation. Such a correlation would be introduced if women's recent use of mammography made them better informed regarding price and if poorly informed women systematically believed the price to be higher or lower than it actually was.

Predicted, rather than actual, prices and insurance coverage were therefore used to compute net price. Sixty-eight telephone number prefixes were used as indicators of approximate market areas. For each prefix area, the mammography price was estimated as the average price reported by women with that prefix who knew, or were willing to guess, the cost of screening mammography in their community. When there were fewer than three such women in a prefix area (a situation that occurred for 16 women), the overall average for the community was used. A dummy variable was included in the prediction equation indicating whether or not the woman had guessed, to allow for the possibility that these women systematically guessed higher or lower than women who claimed to know the price.

The procedure for predicting time cost was identical to that used for predicting money price, and an analogous approach was used to predict values for insurance coverage. All women were asked what kinds of health insurance they had. Fifty-six types of health insurance coverage were identified, and regression analysis (with dummy variables for each type of insurance) was used to estimate the proportion of the price paid by each insurer based on the survey responses of those women who answered the questions. These estimates were then used in place of reported insurance coverage in computing the net price as the product of the charge for mammography and the proportion paid by the woman. This procedure for imputing prices is an instrumental-variables approach that yields consistent estimates of the coefficients of interest.[18] It simultaneously computes missing values, precludes correlation of the regressor with the error term, and specifies demand as a function of the *market* price faced by the woman.

To avoid the exclusion from the sample of the women whose household income was not reported, a regression model based on geographic area as indicated by telephone prefix and sociodemographic characteristics of the woman (age, education, working status, and marital status) was estimated. Predicted incomes based on this equation were used to impute missing values.

Results

Of the 1528 usable interviews, 8 were excluded from all analyses because the age was missing. Approximately 40% of the remaining 1520 women were over the age of 65. The percentages of women, by age, who reported having health insurance that covered screening mammography are shown in Table 1. Over half of the women reported that they had insurance that paid all (31.5%) or part (21.7%) of the cost of a screening mammogram. The older women were slightly less likely than the younger women to report insurance coverage that paid all or part of the cost (50.3% vs 55.2%). The younger women were more likely than the older women to report no health insurance for screening mammograms (28.1% vs 21.4%), and the older women were more likely than the younger women not to know whether their insurance would pay for screening mammograms (28.4% vs 15.7%). Differences were statistically significant (χ^2 with 3 degrees of freedom [df] = 40.1, $P < .001$).

Bivariate relationships between mammography use and economic variables, based on the perceptions of the women themselves, are reported in Tables 2 and 3. Of the 1515 women reporting their mammography use, 40.5% had had a mammogram within the past year. Another 18.7% had had one between 1 and 2 years ago, and only 26.1% had never had a mammogram. The percentages of women who had a mammogram within 1 year, 2 years, more than 2 years ago, and never, by age and insurance coverage, are reported in Table 2. Over half of the women reporting that they did not know whether their insurance covered screen-

ing mammography had never had a mammogram: 53.9% of those under the age of 65 and 54.3% of those aged 65 or older, respectively. Of the women with full coverage, just over half had had mammography in the past year. About a quarter of the women who reported that their insurance did not cover any portion of the cost of screening mammography (or who reported no insurance at all) had never had a mammogram.

The percentages of women who had a mammogram within 1 year, 2 years, more than 2 years ago, and never, by age and income, are given in Table 3. Low-income women were much more likely never to have had a mammogram. Recent mammography (within 2 years) was reported most often among the younger women with incomes above $15 000 annually (68.7%) and least often among the younger women with incomes below $15 000 (42.5%). Age differences were not statistically significant in these analyses, but income and insurance were both significantly related to use when age was controlled (χ^2 with 1 df = 12.8 and 160.7, respectively; both $P < .001$).

Definitions for all variables used in the multivariate analyses are given in Table 4. A total of 1377 women had sufficiently complete data to be included. Means and standard deviations (or percentages for dichotomous variables) are shown for women who did (59.4%) and did not (40.6%) report having had a mammogram in the past 2 years. The statistical significance of the differences between the two groups is also shown for all variables. The average net price was predicted as $31 among users of mammography and $35 among nonusers of mammography. (The average price of mammography in the market areas where the women resided was reported to be $77, among the 1148 women who knew or were willing to guess the price. On average, among the 1032 women who knew whether their insurance covered screening mammography, 61% of the price was believed to be paid by insurance.) Users differed significantly from nonusers with respect to all variables except performance of breast self-examination and time cost. They differed from nonusers most notably with respect to whether they visited a gynecologist regularly (19.9% vs 6.1%), whether they reported that they visited no doctor regularly (3.4% vs 19.1%), and whether they were current smokers (15.0% vs 26.7%). Nonusers also reported lower incomes than users ($19 300 vs $26 300 annually), and a higher proportion of them reported

	Users of Mammography (n = 818)		Nonusers of Mammography (n = 559)		
	Mean or %	SD	Mean or %	SD	P
Age ≥65: 1 if age was >65	36.8%		42.4%		.037
Married: 1 if married or living as married	74.1%		63.5%		<.001
Working: 1 if working full-time or part-time	33.3%		32.0%		.248
Education: mean years of education	13.2	2.2	12.7	2.3	<.001
Smoker: 1 if current smoker	15.0%		26.7%		<.001
Breast self-examination: 1 if performed monthly	50.9%		51.5%		.809
History: mean number of first-degree relatives with breast cancer	.174	.410	.095	.293	<.001
Physician visits: average number of annual visits made to physicians seen regularly	1.90	1.30	1.42	1.30	<.001
No doctor: 1 if no physician was visited regularly	3.4%		19.1%		<.001
Gynecologist: 1 if regularly visited gynecologist	19.9%		6.1%	.239	<.001
Net price: mean out-of-pocket cost of mammography, in $10 increments	$3.07	$1.70	$3.50	$1.71	<.001
Time cost: total hours set aside to obtain a mammogram	1.32	0.39	1.35	0.47	.181
Inconvenience: 1 if weekdays are less convenient than evenings and weekends to obtain mammography	9.0%		15.2%		<.001
Income: mean household income in $10 000 increments	$2.63	$2.08	$1.93	$1.79	<.001
No insurance: 1 if no health insurance	3.5%		10.4%		<.001
Medicare only: 1 if Medicare only	1.6%		7.3%		<.001
Health maintenance organization: 1 if insured through HMO	13.7%		9.3%		.011

that obtaining mammography on weekdays was inconvenient (15.2% vs 9.0%) and that Medicare was their only form of health insurance (7.3% vs 1.6%).

Results of the multivariate analysis are given in Table 5. As predicted by the theory of demand, use was lower among women who faced a higher net money price (odds ratio [OR] = 0.91 per $10 increase in net price, $P = .006$) or who preferred to obtain a mammogram during weekend or evening hours (OR = 0.53, $P = .001$), and higher among women with higher incomes (OR = 1.14, with a 14% increase associated with each $10 000 increment in total household income; $P < .001$). The effect of time cost was negative, as expected, but not statistically significant (OR = 0.86, with a decrease of 14% for each additional hour required; $P = .29$). As a group, the economic variables were highly statistically significant (likelihood ratio with 4 df = 34.0, $P < .001$).

The value of mammography to the woman was also important in determining demand. Use was higher among women with a family history of breast cancer (OR = 2.22, with more than a twofold increase for each first-degree relative with breast cancer; $P < .001$) and among women who visited a gynecologist regularly (OR = 2.59, $P < .001$). Women who visited no doctor regularly and women who were current smokers were less likely to have had mammography (OR = 0.24, $P < .001$ for no doctor; OR = 0.59, $P < .001$ for smokers). More visits to physicians increased the likelihood of mammography (OR = 1.11 per additional visit,

TABLE 5—Odds Ratios for Mammography Use in the Last 2 Years for Women Aged 50–75 y (n = 1377)[a]

Independent Variable	Odds Ratio[b]	95% Confidence Interval
Age ≥65	0.81	0.61, 1.06
Married	1.24	0.95, 1.62
Working	1.01	0.75, 1.37
Education	1.05	0.99, 1.11
Smoker	0.59	0.43, 0.79
Breast self-examination	0.92	0.72, 1.16
History	2.22	1.56, 3.16
Physician visits	1.11	1.00, 1.23
No doctor	0.24	0.15, 0.39
Gynecologist visits	2.59	1.71, 3.92
Net price	0.91	0.90, 0.91
Time cost	0.86	0.64, 1.14
Inconvenience	0.53	0.36, 0.78
Income	1.14	1.06, 1.22

[a]Controlling for county of residence.
[b]Odds ratios are calculated for a one-unit change in continuous variables.

P = .047), but education and marital status were not statistically significant when economic variables were included in the model. When economic variables were excluded from the model, married women were more likely to be users (OR = 1.47, P = .003), as were more educated women (OR = 1.08 for each additional year of education, P = .004).

A variable indicating whether a woman's health insurance covered 50% or more of the price of a mammogram was created. This variable and the interactions between it and those variables measuring time cost, inconvenience, and income were added to the model to test the hypothesis that the importance of economic variables may be greater among women with poor insurance coverage. These interactions were not statistically significant, either individually or as a group (likelihood ratio statistic on 3 df = 5.30, P = .151), suggesting that the effects of time cost, inconvenience, and income on mammography use do not vary with insurance coverage. Similarly, to test the hypothesis that price sensitivity is greater among women with low income, interaction effects between net price, time cost, and inconvenience and a dummy variable for women with household incomes above $15 000 were estimated. The interaction effects were not statistically significant, either individually or as a group (likelihood ratio statistic on 3 df = 0.671, P = .880), suggesting that the effects of net price, time cost, and inconvenience are stable across the income groups.

Discussion

As suggested by the theory of demand, the effects of net price and income on the use of mammography among women aged 50–75, residing in four suburban or rural counties in Washington State, were found to be significantly negative and positive, respectively. The analyses provided no evidence that economic variables are more important for low-income or uninsured women. Instead, effects were stable across the subsets of the population investigated.

The effects of economic variables on use of mammography were found to be important, but they do not suggest that improvements in insurance coverage will dramatically increase the use of screening mammography. The data suggest that insurance coverage for mammography was already quite good among women aged 50 to 75 in Washington State in 1989; over half of the women reported that their insurance paid some (usually 80%) or all of the cost of screening mammography. The new legislation can be expected to increase the average proportion paid by insurance from about 60% to about 80%, which can be expected to decrease the average net price from about $32 to about $16. If the coefficients estimated from these cross-sectional data were to be given a causal interpretation, they would suggest that the percentage of women having a mammogram in the last 2 years might increase in response to improved insurance coverage from about 59% to about 61%, a change of less than 4%. Such an increase would be negligible relative to the secular trend in mammography use. This study provides no evidence that the effect of improved insurance coverage would be greater among low-income women.

However, if physicians are influenced in their referral patterns by the improvement in insurance coverage, the legislation could have a greater impact. A woman might depend on her physician to advise her regarding the value of mammography because the physician has better information than she does about the expected medical benefit of alternative medical services. The physician presumably acts in the best interest of the patient, taking into account her ability to pay for mammography as well as his or her assessment of its value to the patient. This phenomenon has long been recognized as the "agency role" of the physician.[16] However, the physician may be ignorant of the individual woman's ability to pay and reluctant to discuss the issue with her. Instead, the physician may assume that insurance will (or will not) pay for screening mammography and treat all or most women accordingly.

To the extent that the legislative mandates change the physician's assumptions regarding insurance coverage for screening mammography, they could influence physicians' recommendations. State legislation mandating coverage of screening mammography by private insurers and federal legislation mandating such coverage by Medicare may have an important impact on use by creating a "standard of care" recognized by all physicians. The strength of the influence of physicians is evident from the statistical significance of the physician variables in the demand equation. If all physicians were to refer women for mammography at the rates reported for the gynecologists, the estimates obtained here suggest that use of mammography might rise from 59% to about 75%.

Mandating insurance coverage for screening mammography will not compensate for lack of coverage for preventive office visits. As has been shown in previous studies, exposure to physicians, especially to gynecologists, is an important determinant of whether breast cancer screening is done, including clinical breast examination as well as mammography use.[19] In this sample of primarily upper-middle-class White women, 19.1% of the women who had not had mammography in the last 2 years reported seeing no physician regularly, compared with 3.4% of those who had had mammography. Of the nonusers, 10.4% reported having no health insurance at all, compared with 3.5% among the users.

Because variables other than economic variables are important in determining the use of mammography, interventions will still be needed to reach women who do not obtain screening even when it is available at low cost. Among the women in this sample, family history of breast cancer was an important predictor of use, but age was negatively related to use. A family history of breast cancer may contribute to awareness and fear of the disease in a way that aging does not. In addition, women may be more aware of family history than aging as a risk factor. Also notable in this study is the high rate of smoking among the nonusers, 26.7%

compared with 15.0% among the users. In the multivariate analyses, smokers were found to be about half as likely to have had mammography as nonsmokers. This result suggests that compliance with physicians' recommendations for mammography may be an important problem among smokers, perhaps because the procedure is generally performed at a different facility at a later time, providing ample opportunity for noncompliance.

Despite suggestions in the literature that time costs are substantial,[20] time cost was not statistically significant in the demand analysis. However, women who preferred to obtain mammography during evenings or weekends rather than weekdays were significantly less likely to have had mammography during the previous 2 years, suggesting that logistics are indeed important, as has been suggested previously.[21] The relative unimportance of time cost in these analyses may be attributable in part to limitations in its measurement: although total time to obtain a mammogram was measured, the value of time to the woman was not measured.

Other limitations of this study include the cross-sectional, self-report nature of the data and the lack of measures of price and insurance coverage for physicians' services. Most mammography screening is the result of a referral after a visit to a primary-care physician for routine care. The cost of preventive services may remain a barrier to use of breast cancer screening when the cost of mammography services is reduced by insurance. A minor limitation is that, because a direct measure of general health status was not available, the effect of the number of visits to physicians, intended to measure exposure to physicians, may be biased. Similarly, household income was not adjusted for family size because the latter was not measured.

A potential limitation of the study is that women may not be well informed regarding price and insurance coverage for screening mammography. Of interest in this regard is that women who guessed the price differed from women who knew the price by only $2 on average in their estimate of mammography price. Similarly, all but 27 of the 161 members of Group Health Cooperative of Puget Sound who were included in the analyses (10.5% of the sample) knew that their insurance covered 100% of the cost of screening mammography. The Group Health Cooperative is a large health maintenance organization that has had a risk-based breast cancer screening program since 1984.[22] There is no out-of-pocket charge for screening mammography for enrollees in the Group Health Cooperative. Of the 27 patients in this group, 18 did not know whether the Group Health Cooperative covered screening mammography, 5 thought that it did not, and the remaining 4 thought that it covered something less than 100% of the cost. External validation by means of a survey of mammography facilities in the four study communities also confirmed that women were quite knowledgeable. On average, the women reported a price of $77, and the mammographers reported a charge of $63 for screening mammography and $94 for diagnostic mammography. A related concern is that the dummy variables indicating health insurer that were used to predict the proportion of the price of screening mammography paid by insurance are crude measures. As a group in the prediction equation, they explained 24% of the variance, suggesting that they served adequately as instrumental variables.

This study is an attempt to carefully measure mammography price and insurance coverage and to analyze the use of mammography within the conceptual framework of the theory of demand. It provides evidence that cost is indeed important as a barrier to use of mammography. However, it should not be assumed that mandatory coverage of screening mammography will solve the problem of underutilization of breast cancer screening among all women aged 50 to 75. Uninsured women, smokers, and women who do not visit a physician regularly may still have relatively low rates of use. The analyses corroborate the abundant evidence in the literature that the key to use of mammography among women aged 50 to 75 is referral by a physician. □

Using Census and Mortality Data to Target Small Areas for Breast, Colorectal, and Cervical Cancer Screening

ABSTRACT

Objectives. The goal of this study was to develop and validate quantitative models for estimating cancer incidence in small areas.

Methods. The outcome for each cancer site was the incidence of disease that had reached a late stage at the time of diagnosis. Two sets of predictors were used: (1) census-based demographic variables and (2) census-based demographic variables together with the cancer-specific mortality rate.

Results. The best models accounted for a substantial percentage of between-area variability in late-stage rates for cancer of the breast (46%), cervix (61%), and colon/rectum (58%). A validation procedure indicated that correct identification of small areas with high rates of late-stage disease was two to three times more likely when model-based estimates were used than when areas were selected at random.

Conclusions. Additional testing is needed to establish the generality of the geographic targeting methodology developed in this paper. However, there are strong indications that small-area estimation models will be useful in many regions where planners wish to target cancer screening programs on a geographic basis. Introduction

Models for cancer screening programs typically focus on subgroups of the general population on the basis of age- and sex-specific incidence, prevalence, and mortality rates of a particular cancer. Although analyses of individual characteristics indicate who should be screened, small-area analysis can be used to determine where to set up screening programs so that high-risk populations can be more easily recruited. In previous studies of small-area variation in cancer incidence, we quantified the benefits of geographically targeting cancer screening programs, using clustered census tracts as the unit of analysis.[1,2] Those analyses, based on cancer registry data, indicated that the efficiency of breast cancer screening programs can be substantially improved by targeting communities with known high incidence rates.

In many localities, there is no cancer registry to provide incidence data at the community level, so targeting based on known small-area incidence, using the methodology described above, is not possible. Here we describe a two-step technique for making geographic targeting available to these localities:

1. Develop a small-area multiple regression model relating incidence for a particular cancer site to mortality, census-based variables, or both in a locality where cancer registry data are available.
2. Apply the model in the locality of interest, where cancer registry data are not available, and obtain an estimated incidence value for each small area.

The outcome in the regression models is the incidence rate of disease staged as regional or distant at the time of diagnosis (late-stage incidence). The main goal of screening programs is to reduce this rate by identifying in situ and localized cancer in individuals who would otherwise have developed late-stage disease before diagnosis and treatment.

Methods

Geocoding Cancer Incidence and Mortality

New York City cancer incidence data for the years 1976 through 1982 were obtained from the New York State Department of Health Cancer Registry. Mortality data for the years 1977 through 1983 were obtained from the New York City Department of Health. The geographic coding of these data has been previously described.[1] Denominators for small area rates were obtained from 1980 US census data (Summary Tape File 3a).

Incidence, mortality, and census data were aggregated to health areas, administrative units used by the New York City Department of Health. Each health area, with an average population of about 21 000, consists of four to six census tracts. Data were obtained for four of the five boroughs that make up New York City: Bronx, Brooklyn, Manhattan, and

Queens. To reduce rate instability due to small denominators, health areas with a total 1980 population of less than 5000 were excluded from the analysis. Areas in which more than 10% of the total population resided in an institution were also excluded. The 22 health areas excluded by these criteria contained 4.2% of the total population of the four boroughs. The 319 health areas that were included contained a total population of 6 637 686 in 1980.

Rate Calculation

It is customary to adjust for age when comparing geographic variability in cancer rates. However, when targeting geographic areas for screening service delivery, a concentration of age groups at higher risk for a particular cancer should be considered as part of the planning process. We therefore calculated crude age-truncated rates for each area by dividing the total number of incident late-stage cases at or above a specific age by the total area population of the appropriate sex at or above the same age. For cervical cancer, we used the incidence of invasive disease as the measure of late stage. For breast and colorectal cancer, late stage was defined according to the Cancer Registry categories of regional or distant disease.

For each cancer site, an age-truncated crude late-stage incidence rate and an age-truncated crude mortality rate were calculated. For breast cancer, incidence and mortality rates were calculated for women aged 35 years and older, for cervical cancer, rates were calculated for women aged 20 years and older; for colorectal cancer, we combined men and women aged 45 years and older in calculating rates. No upper age limit was set for any site. These age-truncated rates include more than 95% of registry cases for each of the three sites. The total number of late-stage cases used for rate calculation was 11 634 for breast cancer, 16 140 for colorectal cancer, and 3640 for cervical cancer. For mortality rate calculation, the numerator for each cancer site represents all individuals for whom the primary cause of death was cancer of that site during the period 1977 through 1983: 9132 for breast cancer, 9212 for colorectal cancer, and 1285 for cervical cancer. Incidence data and mortality data were not linked: the numerator for each mortality rate includes all deaths for that cancer site in the stated time period, not just deaths of individuals reported to the Cancer Registry during the period for which incidence rates were calculated.

All rates are expressed in terms of yearly averages per 100 000 population. The formula for rate calculation is

$$[(N/7)/T] \cdot 100\,000,$$

where N is the total number of late-stage cases in a given health area for a particular cancer site among individuals in the designated age group during the 7-year study period and T is the total 1980 population in the health area for the site-defined age and sex group. Hereinafter, age-truncated late-stage incidence rates for breast and colorectal cancer and the rate of invasive cervical cancer will be referred to as late-stage rates.

Selection of Predictors for Use in Models to Estimate Late-Stage Incidence Rates

In choosing census-based predictors, we were guided by two criteria: known etiologic relationship to one or more of the three cancers under consideration and absence of multicollinearity among predictors. We were aided in variable selection by previous research that identified dimensions of demography and housing characteristics in New York City.[3] Beginning with the 14 census-based variables that defined these dimensions, we used multiple regression analysis to isolate a subset of four variables that met the above criteria and that, when used together, accounted for nearly as much variability (adjusted R^2) in each of the late-stage rates as the full set of 14 variables: (1) percentage of the population aged 65 years and older; (2) percentage of households with income higher than $50 000 per year; (3) percentage of the population (aged 15 years and older) divorced or separated; and (4) percentage of women in the labor force with one or more children aged 16 years or younger. Descriptive statistics for these variables, together with mortality rates and late-stage incidence rates, are shown in Table 1. For analytic purposes, we applied log or square root transformations to skewed variables to approximate a normal distribution, as indicated in Table 1.

Data from all four boroughs were used to develop a multiple regression model for each of the three late-stage rates, with the four census variables and the appropriate mortality rate as predictors. To simulate a situation in which targeting is to be done in a locality for which cause-specific mortality data are not available or not accessible, we also developed a model for each cancer in which only census variables were used as predictors. The addition of interaction terms did not improve the adjusted R^2 values for any of the regression models.

TABLE 1—Descriptive Statistics for Outcome and Predictor Variables (n = 319 Health Areas)

	Mean	SD
Outcome variables—incidence rates[a]		
Late-stage breast cancer	91.72	23.92
Invasive cervical cancer[b]	22.44	12.76
Late-stage colorectal cancer	94.48	24.58
Predictors—mortality rates[a]		
Breast cancer[b]	71.66	21.85
Cervical cancer[b]	8.22	6.68
Colorectal cancer	79.22	21.32
Predictors—census variables		
% persons aged 15+ y divorced or separated	11.98	4.81
% working mothers with children <18 y	29.48	10.43
% households with income above $50 000[c]	3.30	4.76
% persons aged 65 y and older	13.16	5.70

[a]Expressed as cases per 100 000 population.
[b]A square root transformation was applied to this variable in the regression models.
[c]A log transformation was applied to this variable in the regression models.

Model Validation

For each cancer site, we used the following procedure to determine the accuracy with which a model developed in one geographical area could predict late-stage rates in another area.

1. One of the four boroughs of New York City—for example, Queens—was designated as the geographic area for which estimated rates of late-stage disease for a particular site—say breast cancer—were needed.

2. A multiple regression model for estimating late-stage breast cancer rates was developed, using only data from the other three boroughs—in this case, Bronx, Manhattan, and Brooklyn.

3. The regression model was used to calculate an estimated late-stage rate for each health area in Queens. This was done by taking the known value of each predictor for a particular health area in Queens and multiplying by the appropriate unstandardized regression coefficient specified in the three-borough model. These

TABLE 2—Correlation[a] between Estimated and Actual Late-Stage Incidence Rates, Based on Models with Mortality and Census Variables and Census Variables Only

[a]Pearson's product-moment correlation coefficient (*r*).

terms were then summed and the value of the model intercept was added, yielding the estimated late-stage rate for that health area. This process was repeated for each health area in Queens.

4. The model was validated by correlating the estimated late-stage rates for the 74 health areas of Queens, based on the model developed with data from the other three boroughs, with the actual late-stage rates in those same areas, based on data from the New York State Department of Health Cancer Registry.

For each cancer site, the above steps were repeated. Data from each unique combination of three boroughs were used to build the model and obtain an estimated rate of late-stage disease for each health area in the excluded borough. For each site and borough, one model was built with the four census-based variables and the site-specific mortality rate as predictors; the other model included only the four census-based predictors.

Results

The correlation between actual late-stage rates and late-stage rates estimated from the appropriate model is shown for each combination of borough and cancer site in Table 2. In general, the association between estimated and actual rates was highest for invasive cervical cancer, for which all correlations were greater than .7 when mortality and census data were used in the estimation model. As shown in the table, all correlations were greater than .6 even when census data alone were used. The lowest correlations were obtained for the breast cancer models: the mean correlation was .65 when mortality was included and .55 when only census variables were used. For colorectal cancer, the correlation between estimated and actual late-stage rates varied from a low of .68 in Manhattan to a high of .80 in the Bronx when mortality and census data were used. When only census data were used in the model, correlations ranged from .44 in Manhattan to .83 in the Bronx.

From a planner's perspective the key question with respect to model validity is, What is the relationship between actual and estimated rates *in the areas targeted to receive a particular service?* To answer this question, we follow a hypothetical scenario in which planners have decided to target for screening the health areas with the highest estimated late-stage rates, defined as those areas in the top quintile (20%).

TABLE 3—Accuracy of Targeting on the Basis of Estimation Models

	Model Type			
	Census and Mortality		Census Only	
Borough	Top 20%	Top 40%	Top 20%	Top 40%

Queens	60	73	53	80
Mean	65	86	60	77

Note. Numbers in table are percentages of targeted health areas (areas with estimated late-stage rates in the top 20%) that fell into the top 20% or top 40% of all health areas with respect to actual late-stage incidence rates. Higher percentages indicate greater accuracy.

To determine the accuracy of this targeting process, we calculated the percentage of targeted areas in each borough that fell in (1) the upper 20% of health areas with respect to *actual* late-stage rates and (2) the upper 40% of health areas with respect to *actual* late-stage rates. If the model provided perfect predictions, 100% of the targeted areas would be in the upper 20% with respect to actual late-stage rates. In the worst-case scenario, in which the model had no predictive power, one would expect that on average only 20% of the targeted areas would fall in the upper quintile of actual late-stage rates—the proportion expected by chance. Similarly, with perfect prediction, 100% of the targeted areas would be in the upper 40% of areas with respect to actual late-stage rates; in the worst case, only 40% of the targeted areas would be in the upper two quintiles of actual late-stage rates. The normal approximation to the binomial distribution was used to determine whether the actual number of targeted areas in the upper quintile was significantly greater than the number expected by chance. The results are shown in Table 3.

The concordance between targeted areas and the upper quintile of actual late-stage rates is greatest for invasive cervical and colorectal cancer and lowest for breast cancer. For all cancer sites, the concordance between upper quintile of estimated and actual rates is considerably better than what would be expected by chance ($P < .00001$). For example, as indicated in the first row, first column of Table 3, 45% of the areas in the upper quintile of estimated late-stage rates of breast cancer in Brooklyn (the targeted areas) were also in the upper quintile of actual late-stage rates—more than twice the chance expectation of 20%. As indicated in the first row, second column, 81% of the health areas that were in the upper quintile with respect to estimated late-stage rates were either in the highest or second highest quintile in terms of actual late-stage rates, more than twice the 40% rate of concordance expected by chance. Consistent with the correlational analyses (Table 2), concordance between estimated and actual rates is better in models using mortality and census-based predictors than in models using only census-based predictors.

Maps of the results with respect to one of the outcomes, invasive cervical cancer, are shown for the Bronx (Figure 1), providing visual confirmation of the strong relationship between estimated and actual rates. The maps also show that the high-rate areas that would be targeted for screening in the Bronx tend to cluster geographically. Such clustering should enhance the efficiency with which screening resources can be geographically allocated.

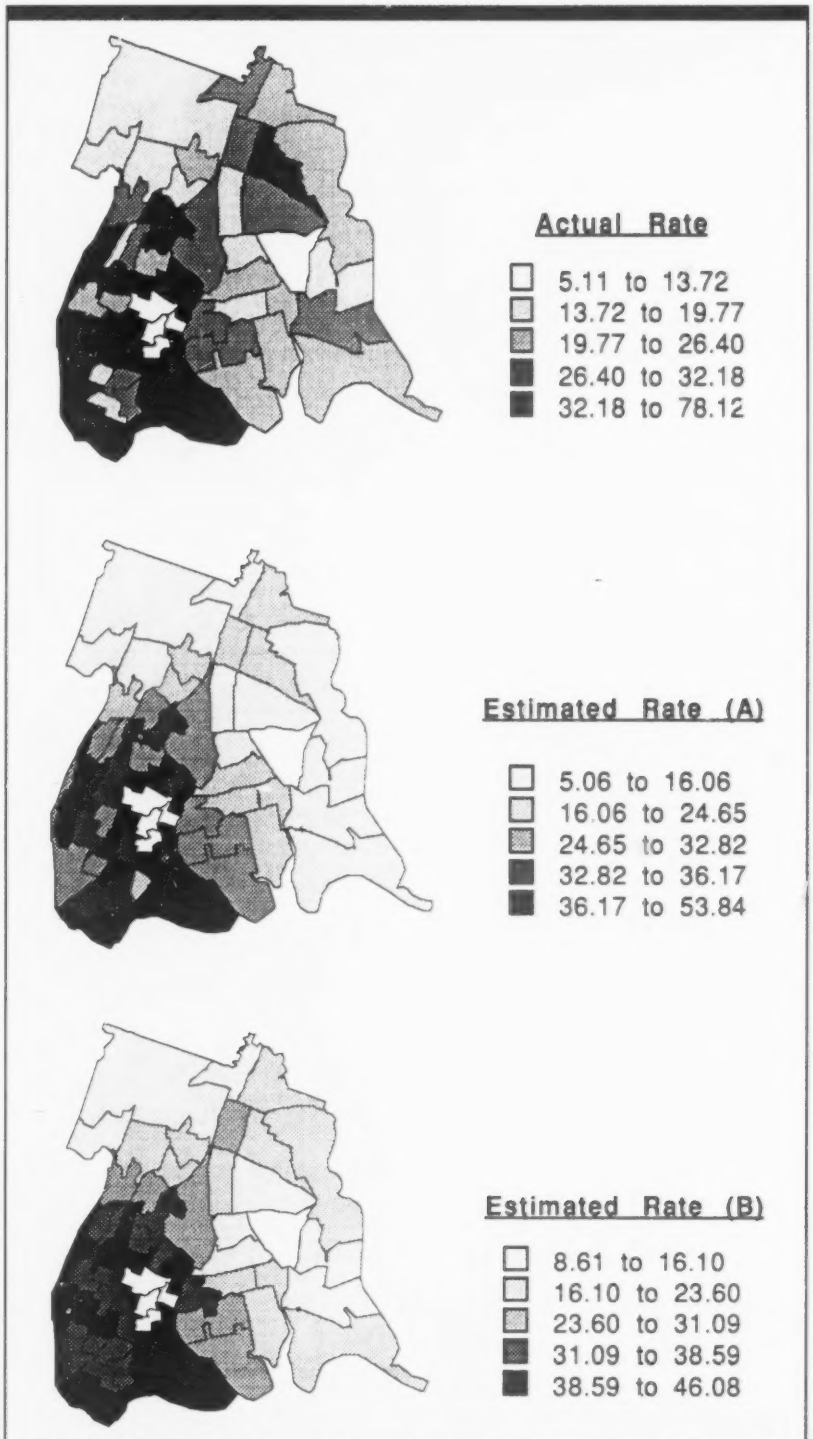
"Best" Models

In the validation process described above, several models were developed for each cancer site, each based on data from three boroughs. Given the apparent viability of targeting small areas on the basis of census data alone or census and mortality data, the question arises, What specific model should be used in applying this approach in a city or region in which cancer registry data are not available?

To develop a set of "best" models for use by planners, we used data from all four boroughs to maximize the stability of parameter estimates. As shown in Table 4, the four census variables alone explained a statistically significant proportion of variability in each of the late-stage rates ($P < .001$): the adjusted R^2 was .33 for breast cancer, .54 for invasive cervical cancer, and .39 for colorectal cancer. In the models using breast cancer and colorectal cancer as outcomes, only one census variable accounted for a significant proportion of variability in late-stage rates—the percentage of the population in the health area that was 65 and older. For cervical cancer, two census variables were significantly associated with the rate of invasive disease: (1) percentage of the population divorced or separated and (2) income level—poor areas had significantly higher rates than wealthier areas.

For each cancer site, the addition of the site-specific mortality rate to the model added significantly to the proportion of explained variability. The greatest increment in adjusted R^2 resulting from the addition of mortality rate as a predictor occurred for colorectal cancer (19%). Moreover, for this cancer site two census variables that were not significant in the census-only model, percentage of working mothers and percentage of population divorced or separated, did make significant contributions to R^2 when the mortality rate was added.

When the site-specific mortality rate was used without census variables in the model, a substantial proportion of variability in late-stage rates was accounted



Note. Areas with rates in the upper quintile (20%) of all health areas—those that would be targeted in a screening program for cervical cancer—are shown in the darkest shading. Unshaded (white) areas had populations that did not meet criteria for inclusion in the analysis. Estimated rates, based on models developed using data from health areas in Brooklyn, Manhattan, and Queens, are shown in the two lower maps. In model A, estimated rates were based on regression analysis in which both mortality rates and census variables were used as predictors. In model B, rates were based on an analysis in which only census variables were used.

FIGURE 1—Geographical distribution of actual and estimated rates of invasive cervical cancer in health areas in the Bronx (n = 57).

TABLE 4—Multiple Regression Models for Estimating Late-Stage Incidence

Model Type	Regression Coefficient (Unstandardized) Mortality	Divorced/ Separated	Working Mother	High Income	Elderly	Intercept	R^2
Breast cancer							
Census and mortality	7.01	...	...	...	10.46	−3.79	.46
Census only		...	...	...	12.47	30.72	.33
Cervical cancer							
Census and mortality	.39	.09	...	−.52	...	3.00	.61
Census only		.13	...	−.67	...	3.75	.54
Colorectal cancer							
Census and mortality	.60	−.58	.30	...	10.86	6.57	.58
Census only		...	...	...	19.33	26.07	.39

Note. The regression model accounts for a significant proportion of the variability (R^2) in late-stage incidence rate in all models ($P < .001$). R^2 values are adjusted for number of variables in model. Coefficients of all variables shown have a significant relationship to the outcome variable in the model ($P < .05$). Ellipsis points indicate a variable excluded from the final model because its effect when included in a preliminary analysis was nonsignificant.

TABLE 5—Multiple Regression Models for Estimating Late-Stage Incidence Based Only on Mortality

Cancer	Mortality Regression Coefficient	Intercept	R^2
Breast	10.03	8.07	.37
Cervical	.75	2.58	.41
Colorectal	.81	30.24	.49

Note. The regression model accounts for a significant proportion of the variability (R^2) in late-stage incidence rate in all models ($P < .001$). R^2 values are adjusted for number of variables in model.

for: 37%, 41%, and 49% for cancers of the breast, cervix, and colon/rectum, respectively (Table 5). Thus, site-specific mortality data could be used without census data to target areas where late-stage disease is high. However, since census data are available everywhere in the United States, and since the addition of census-based variables adds 10% to 20% to the explained variability in the models, there should be no need to develop or implement mortality-only models. The only situation in which such models might be valuable is one in which (1) there has been rapid change in the demographic characteristics of the neighborhoods under consideration for community-based screening programs and (2) available census data were collected too long ago to capture these changes.

To test the possibility that there was a spurious inflation of R^2 in the models owing to the use of census-based population counts in the calculation of both predictors and outcome rates, we entered the factor $1/N$ in each equation, where N was the same value used in the denominator of the age-truncated rate. The results indicated that there was no spurious correlation: in each model the significance of each predictor was unaffected by the addition of $1/N$, and the values of the regression coefficients remained approximately the same as those shown in Table 4. However, for two of the cancer sites, breast and cervix, the term $1/N$ was itself significant in the model. In the case of late-stage breast cancer, the adjusted R^2 was increased by 2% by the addition of $1/N$ to the model. For both sites, the sign of the regression coefficient for $1/N$ was positive, indicating that when the other variables in the model were held constant in the regression model, late-stage rates tended to be higher in areas of low population. This suggests that low population, or some factor associated with it, makes an independent contribution to the risk of late-stage disease.

Are the Models Applicable to Other Regions?

One test of the potential generality of the models developed in this paper is whether model-based estimates are accurate in geographic areas that differ in terms of demography, outcome rates, or both from the geographic areas in which the models were developed.

To determine the extent of differences among the four boroughs used in the model validation process, we performed a series of one-way analyses of variance to compare mean values of site-specific mortality late-stage rates and each of the census-based predictors in the four boroughs of New York City, using health area as the unit of analysis. The results indicate that the four boroughs differed substantially in terms of key demographic and outcome characteristics. All pairs of boroughs except Manhattan and Brooklyn differed significantly in terms of mean values of at least one late-stage rate. Four of the six pairs differed in terms of at least one site-specific mortality rate, and all six pairs differed in terms of mean value of at least one demographic characteristic.

Discussion

The results indicate that a quantitative model developed in one geographically defined area on the basis of available census data can be used to obtain good estimates of late-stage rates for breast, colon/rectum, and cervical cancer in another geographic area. The accuracy of estimation is improved for all three cancer sites when the site-specific mortality rate is included as a predictor. Because disease that has progressed to a late stage at the time of detection is likely to result in death, it is not surprising that mortality data considerably enhance the power of the model to estimate late-stage rates. More unexpected is the finding that without mortality rate as a predictor, and using only four variables derived from census data, the models can account for a substantial proportion of geographic variability in late-stage rates of all three cancer sites. Therefore, even in localities without ready access to population-based mortality data, it should be possible to estimate late-stage rates accurately and to successfully target screening programs to high-risk communities. However, all of the areas used in developing and testing of the models presented in this paper are located in New York City. Ultimately, these models will be useful only if they can be applied in targeting community-based screening programs in other regions of the United States and the world. Thorough testing will require comparison of model-based estimates with actual rates in other regions of the country where cancer registry data are available.

There are a number of indications that these models will work well in other geographical regions. First, the results demonstrate that the four boroughs of New York City differ substantially along

the dimensions of demography and cancer outcome examined in this paper. This indicates that the models are robust with respect to demographic and disease characteristics of the region for which estimates of late-stage cancer are required.

An examination of the predictors used to estimate late-stage rates also suggests that the models will be widely applicable. Site-specific mortality rates would be expected to be strongly associated with late-stage incidence in any community. For breast and colorectal cancer, an increase in overall incidence as well as late-stage disease with advancing age has been well documented,[4,5] so the percentage of an area's population that is 65 years old or older would be expected to predict late-stage rates for these two sites in any locality. Similarly, invasive cervical cancer and late-stage colorectal cancer are known to be more prevalent in poor populations,[4,6] so the association of low income and socioeconomic factors with late-stage incidence that is quantified in the models developed in New York City should apply in other areas as well.

However, the relationship between predictors and cancer outcomes will no doubt be attenuated if the models are applied to regions in which there is little variability, as would be the case in, say, a region made up of middle-income suburban communities. The models developed in this paper are therefore most appropriate in areas that contain substantial demographic variability among the communities under consideration for targeting.

The finding that performance of the models was poorest for breast cancer is consistent with the results of a previous analysis,[2] which indicated that of the three cancer sites examined, the year-to-year reliability of late-stage rates was lowest for breast cancer. When the reliability of any outcome measure is relatively low, the ability to account for variability in the outcome on the basis of other measures will be limited.[7] However, the results indicate that even for breast cancer, the models correctly identified high-risk geographic areas at considerably better than twice the level that would be expected by chance.

Methods used in some small-area analyses involving health outcomes have been criticized for failing to adequately test the null hypothesis that observed differences between late-stage rates are due to random variation.[8,9] When data from multiple years are available, the method we have developed to quantify year-to-year rate stability[2] and that was applied to the outcomes examined in this paper can be used to directly test the null hypothesis of random between-area variation.

Can the estimation models be improved? Some of the unexplained variability in each model may reflect measurement error or factors that are specific to particular geographic regions. However, it may be possible to improve the R^2 value of the models by including additional demographic factors. The finding that low population is related to high rates of late-stage disease, after controlling for sociodemographic factors, suggests one direction for future research. In New York City, health area boundaries were originally defined in such a way that each area had a total population of approximately 20 000. Health areas with low population have resulted from loss of housing in certain areas.[10] The impact of loss of housing and social disintegration on the health status of individuals who remain in these areas is well documented.[11] It may be that census-based measures of housing loss or other indicators of deterioration over time will improve the ability of estimation models to identify appropriate sites for targeting community-based cancer screening and other health-related intervention programs.

In conclusion, there is good reason to believe that the relationships among late-stage cancer incidence, mortality, and demographic characteristics that have been quantified in the models presented in this paper will apply in many urban and nonurban regions. If this hypothesis can be confirmed in future research, geographically based targeting of cancer screening programs will no longer be limited to areas in which population-based cancer registries have been established. □

Acknowledgments

This investigation was supported in part by NCI grant J1 R01 CA 46586.

We would like to express our thanks to Philip C. Nasca, PhD, Director, Bureau of Cancer Epidemiology, New York State Department of Health, and to William Burnett, MD, Director, New York State Cancer Incidence Registry, who made Registry information available and generously shared their expertise in the analysis of these data. We thank Drs Patricia Cohen, Bruce Link, and Rodrick Wallace and two anonymous reviewers for their valuable comments on earlier versions of the manuscript.

Changes in the Use of Screening Mammography: Evidence from the 1987 and 1990 National Health Interview Surveys

Nancy Breen, PhD, and Larry Kessler, ScD

ABSTRACT

Objectives. **Mammography rates reported by women in the National Health Interview Surveys of 1990 and 1987 are examined. Why this screening modality is not more frequently used is explored.**

Methods. **Data from the 1987 and 1990 National Health Interview Surveys, conducted by the National Center for Health Statistics, are cross-tabulated and compared.**

Results. **In 1987, approximately 17% of women over 40 years of age reported having had a screening mammogram in the previous year. In 1990, the rate doubled. Race declined in importance; income and education remained strong, positive predictors of screening.**

Conclusions. **Despite this dramatic increase, two thirds of women are not having screening mammograms. Use was not higher primarily because women did not realize that screening mammography tests for breast cancer in asymptomatic women. Primary care physicians are the main source of health education for screening mammography. The data suggest that public health programs to promote screening mammography should especially target primary care physicians and women with low incomes and education. Likewise, health care providers should ensure that their patients are referred to facilities that deliver high-quality mammography at low cost to make the procedure more accessible. (*Am J Public Health.* 1994;84:62-67)**

Introduction

Since publication of the results of the New York Health Insurance Plan randomized trial for breast cancer screening in 1982, mammography has gained acceptance in the medical community[1,2] and has increasingly been used for the early detection of breast cancer in asymptomatic women.[3,4] That trial provided the first scientific evidence that mammography and breast physical exams reduce mortality from breast cancer in women 50 years of age and older and possibly in women 40 to 49 years of age.[5-7]

Only with the release of the National Health Interview Survey (NHIS) Public Use Tape in 1990 did trend analysis of the use of mammography by age, race, and socioeconomic status (SES) with a nationally representative sample become possible. Previous researchers had analyzed change over time in use of breast cancer screening modalities based on local, self-selected, or convenience samples.[3,8-10]

Each year, the NHIS includes supplemental questions on different topics of interest to other federal agencies. The National Cancer Institute (NCI) sponsored a cancer control supplement to the 1987 NHIS to assess knowledge of, attitudes toward, and use of a wide variety of cancer screening modalities, including breast physical examination and, for the first time, mammography. The health promotion and disease prevention supplement to the 1990 NHIS included similar questions on breast cancer screening.

In 1987, women were asked about all three widely recommended breast cancer screening modalities: mammography, breast physical examination, and breast self-examination. These and subsequent data consistently showed that age, race, income, and education contribute in predictable ways to whether women are screened for breast cancer.[11-14] Women who have had a mammogram are likely to be younger[3,11,15-17] (although older women are more likely to develop breast cancer[3,11,18]) and White[4,11] and to have a higher income, more education, a usual source of health care,[4,11,16,19,20] and a regular physician (especially a gynecologist or internist).[10] Finally, women enrolled in health maintenance organizations in 1987 were nearly twice as likely to have had a mammogram and 11% more likely to have had a breast physical examination than women relying on other sources of health care.[21]

A recent analysis of 1990 NHIS data used multivariate logistic regression to estimate the likelihood of women 40 to 75 years of age having regular mammograms. Higher income, use of other kinds of screening, having a regular source of health care, living in the West or a metropolitan area, and engaging in healthy practices were all associated with regular mammography.[22]

Our study measured and compared the proportion of White, Black, and Hispanic women who reported being screened in 1987 and 1990. The detailed trend analysis reported here is designed to encourage other researchers to probe further the determinants of use of mammography and breast physical examination. Trends by age, race, usual source of health care, rural or urban location, family income, and educational attainment are examined and their interactions explored.

The National Health Interview Survey

The NHIS is a continuing annual nationwide survey of approximately 49 000 households in the civilian noninstitutionalized population of the United States conducted by the National Center for Health Statistics.[23] Information is gathered on health knowledge, attitudes, and practices for various population groups, including those defined by age, sex, race, family income, geographic region, and place of residence.[24,25]

Blacks are regularly oversampled for the NHIS, but Hispanics are not. The 1987 cancer control supplement oversampled the Hispanic population in order to obtain more accurate estimates for that group. Data presented here come from this supplement, administered to half of the households in the survey, and the health promotion and disease prevention supplement of 1990, administered to all households. Only women 40 years of age and older (6771 respondents in 1987 and 12 808 in 1990) were asked questions on breast cancer screening.

Data from the two surveys are comparable except for minor changes in the questions.[24,25] The series of questions in 1987 began by defining a mammography and then asking (as screening question) respondents whether they had ever heard of mammography. If not, respondents were not asked whether they had ever had one. This may have reduced the response rate slightly in 1987 relative to 1990, when the screening question was not included; however, other studies show similar recent dramatic increases in rates of screening mammography.[3,26,27] Mammography questions were also asked in the 1992 and 1993 NHIS and will be included in the 1994 version.

Methods

The SUDAAN program was used for this analysis. Sample design information was used to calculate population estimates for the 1987 and 1990 NHIS, including proportions and design-appropriate standard errors and tests of significance.[28]

The SUDAAN logistic regression procedure was used to test the hypothesis of group differences in a regression model; screening behavior in the previous year was the dependent variable, and race or ethnicity, income, education, or an interaction was the predictor variable (at the conventional $P < .05$ significance level).

The hypothesis of differences between years was tested with 95% confidence intervals.

Results

The proportion of women over 40 years old who used mammography almost doubled between 1987 and 1990 (Table 1), from 17% to 33%. (Approximately 3% had nonscreening mammograms in both years.) Differences reported are statistically significant unless otherwise indicated. In both years, rates of use peaked in the sixth decade of life and declined thereafter.

Rates of screening mammography among women who reported no usual source of health care more than doubled between 1987 and 1990, from 6% to 15%. They also doubled for women with a usual source of health care, from 18% to 36%.

Mammogram Use among Blacks, Whites, and Hispanics

Rates of mammography screening most closely reflect the behavior of White women because they constituted 79% of all respondents in 1987 and 80% in 1990. Eighteen percent reported being screened in 1987 and 33% in 1990.

Black and Hispanic women reported having a screening mammography in the previous year less often than White women in 1987. Between 1987 and 1990, however, their rates of use increased more rapidly than did those of White women so that, in 1990, all three racial-ethnic groups reported screening mammography at nearly the same rate. Proportional differences by race and ethnic group were statistically significant in 1987 but not in 1990.

Use of Screening by Income, Education, and Location

Table 1 shows use of screening mammograms by three educational levels: less than 12 years of school completed, 12 years completed, and more than 12 years completed. Although greater use was associated with more education in both surveys, the gap diminished relatively (but not absolutely) between 1987 and 1990.

[a]For 1990, $P < .01$.
[b]For 1987, $P < .01$.
[c]For 1987 and 1990, $P < .01$.

A single income cutpoint of $20 000 was used in this analysis, although more detailed income data show similar patterns.[13] Twice as many women whose family incomes were $20 000 or more in 1987 reported a screening mammogram as those whose family incomes were lower. Since mammography use more than doubled for women in lower income families and did not double for women in higher income families, the gap in screening rates by income declined. However, it remained statistically significant.

In both 1987 and 1990, women living in metropolitan areas reported more frequent recent screening with mammography than their nonmetro counterparts, even after age, race, income, and education were controlled. This is not surprising since facilities tend to be concentrated in high-income urban areas.[29]

Income, Education, and Race

Because they are correlated with race and ethnicity in the United States, income and education for women in the three predominant race and ethnic groups were examined and compared. Table 2 shows the proportion of White, Black, and Hispanic women more than 40 years of age who reported a screening mammogram by family income and educational attainment.

Women in families with annual incomes of $20 000 or more in 1987 reported using mammography at higher rates than women in families with lower incomes. Between 1987 and 1990, screening mammography rates rose 23 percentage points each for Black and Hispanic women and 16 percentage points for White women. Among White, Black, and Hispanic women living in households with incomes of less than $20 000, rates rose 12%, 13%, and 14%, respectively, so that by 1990 all three groups had risen to 24%. Differences by race and ethnicity were not statistically significant in either year after income and education were controlled.

Hispanic women reported using mammography screening at the lowest rates of any of the race and ethnic groups under study, yet mammography use increased most among Hispanic women between 1987 and 1990.

The greatest increase in use of screening mammography associated with education occurred among Black women with less than a high school education. Among Hispanic women, the greatest gains were for those with a high school education. Among White women, gains were greater among those who were less educated and declined with higher educational attainment.

Table 3 shows women who reported a screening mammogram, by age group, race, and percentage of these who graduated from high school. Older Black women showed the greatest gain between 1987 and 1990. The decline in mammography use associated with age in 1987 was far less apparent among Black women in 1990, except for those 80 years of age or older. Although screening among Black women increased concurrently with a greater proportion graduating from high school in the 40 to 44 and 50 to 54 age cohorts, it is noteworthy that mammography rates rose for every age cohort whether or not rates of high school graduation rose.

Breast Physical Examination

The trend in use of breast physical examination reported in the NHIS was analyzed by Makuc et al.,[18] who detected a greater increase in breast exams among Black than White women between 1973 and 1985, resulting in higher rates among Black women in 1985.

Questions on breast physical examination asked in the 1987 NHIS were slightly different in 1990. Whether women had ever heard of breast physical examination and whether they used it for screening as opposed to diagnostic purposes were asked only in 1987. In that survey, 6.9% of women reported that they had never heard of breast physical examination (13% of women had never heard of a mammogram). Of the women who reported having a breast physical examination, only 6% said that it was not for screening purposes.[11]

Since the 1990 data do not distinguish between screening and diagnostic breast physical examinations, the rate of all exams in both years is reported. Use of breast physical examination exceeded mammography in both years. Fifty percent of women more than 40 years of age reported an annual breast physical examination by a health care practitioner in 1987, and this proportion rose to 65% in 1990.

A larger percentage of Black than White or Hispanic women reported hav-

ing breast physical examinations in 1987 and 1990, and their rate of screening also increased most. Although rates were lower for White and Hispanic women than for Black women, all three groups showed increased use of breast physical examination.

Reasons for Not Having Mammograms

Of women more than 40 years of age who had not had a mammogram in the last 3 years, only 7.2% in 1987 and 5.7% in 1990 had ever had a mammogram. In both 1987 and 1990, the same question was asked: What is the most important reason why you have never had a mammogram/ not had a mammogram in the past few years? The 1987 survey provided 17 precoded categories (including other and don't know), and the 1990 survey provided 14 (including other, don't know, and refused).

Women's responses are grouped into six general categories in Table 4 characterizing why they did not have a mammogram in the 3 years prior to the survey: (1) lack of physician's recommendation, (2) lack of knowledge that screening mammography is for asymptomatic women, (3) fear or discomfort, (4) expense, (5) put it off, and (6) other.

The most frequently reported reason was no need or no breast problems. Forty-eight percent of respondents in 1987 and 41% in 1990 lacked knowledge of the need for breast cancer screening. Previous studies have shown that women who do not have screening mammograms are more likely to believe that the procedure is unnecessary in the absence of symptoms than women who are screened.[30] Thirty-one percent of women reported that their physician did not recommend a mammogram.

Few women reported that they did not have a mammogram because they felt fear or discomfort, and the proportion dropped, from 2.5% to 1.7%, between 1987 and 1990. Although rates remained small, the proportion of women who cited expense as a reason for not having a mammogram more than doubled from 2.7% in 1987 to 7.2% in 1990.

Discussion

Despite encouraging recent increases in screening, two thirds of women more than 40 years of age in 1990 did not have a screening mammogram in the previous year, and 38% had *never* had a mammogram. Age, cost, and physician recommendation are key reasons why women do not undergo screening. The discussion to follow explores links between these factors and strategies to increase the rate of screening mammography.

Age is most strongly associated with breast cancer in women. Data from the Surveillance, Epidemiology, and End Results Program of the NCI show that the age-adjusted incidence rate for invasive breast cancer among women 65 to 74 years of age (399 per 100 000) was twice that of women 35 to 64 years of age (193 per 100 000) during 1984 to 1987.[3] Although screening rates doubled for older women, they remained below those of younger women. Benefits of mammogra-

phy screening for women 50 to 74 years of age have been proven in clinical trials.[31] The benefits for women 75 years of age or older are unknown; however, a 1990 forum for breast cancer screening in older women recommended annual breast physical examination and biennial mammography for women in this age group in good general health.[32] Given the finding that strong physician recommendation is the most important health education intervention for breast cancer screening,[33] especially for older women,[34] it is critical for practitioners to be aware of and convey this information to their patients and to recommend regular mammograms accordingly.

Logistic regression analyses of NHIS data from 1987[13] and 1990,[22] as well as other surveys,[35,36] support our findings that gaps by race and ethnicity closed between 1987 and 1990, leaving income and education to explain the significant differences in screening mammography in 1990. A study conducted in Los Angeles also found virtually the same rates of screening mammography for high-SES White, Black, and Hispanic women, although Hispanic women were screened at lower rates than Black or White women in the low-SES group.[12] Providers could help increase rates of mammography use, but they are often unaware of insurance coverage or state benefits for screening mammography.[37,38]

This complex picture shows subgroups of women with different rates of screening mammography, underlying beliefs about mammography, and ability to pay. The average charge for a screening mammography is between $100 and $125.[39] Yet radiologists can deliver high-quality screening mammography at much lower cost (between $50 and $65).[40–42]

Although few women reported cost as the major reason that they did not have a mammogram, it may be more important than NHIS data suggest since the survey question precludes reporting cost unless it is the foremost concern. Other studies have found that women's concerns about the cost of mammography[12] and willingness to pay $75 to $100[33] are significant in their decision to have regular mammograms. Physicians may fail to recommend mammography if, in their judgment, a woman will not comply or is not able to pay.[9] A study of breast cancer screening use by Latina community health center clients underscores the importance of providers in initiating discussion and encouraging regular screening.[43] The small proportion of women who reported cost as a deterrent in the NHIS may reflect the phenomenon that providers do not recommend screening mammograms to patients they believe will not comply.

Women are more likely to undergo regular mammography screening if they believe that their doctors support it[26,30,33,34] or think that the test is efficacious for and accessible to them.[26,30,33] Surveys that directly measured whether a physician's recommendation promoted mammography use among women found that 97%[8] and 94%[44] of respondents had a mammography after their doctor recommended it; a survey of poor urban Black women found that 85% would have a mammogram if their physician recommended one.[45] Nevertheless, most (63%) physicians queried in 1989 indicated that they did not recommend screening mammography.[2]

Most women with at least one mammogram report that they had it because their physician so recommended.[26,46] Strategies to promote regular use of mammography need to target both women and physicians.[33] Self-referral to mammography facilities is unusual; the NCI National Mammography Survey found that only 7.7% of all mammography clients were self-referred in 1991.[47]

Primary care physicians serve as gatekeepers in deciding whether to recommend procedures to their patients. Physicians may effectively filter out women with low income and education by not discussing or recommending mammography to them. Hence, in Table 4, both lack of physician recommendation and women's lack of knowledge regarding screening mammography constitute missed clinical opportunities for physicians or other health care providers.

If the procedure is to be successful, women need to understand the importance of routine screening for asymptomatic women. Training in breast physical examination is needed for physicians[48,49] as well as for the women themselves.[50,51] Physicians also need to include such examinations in their regular physicals.[16]

A recent review of the state legislative movement to make screening mammography a basic health insurance benefit argues that a clear view of attitudes toward mammography requires that physicians and age-eligible women take full advantage of benefits.[52] This requires a health care delivery system that provides confidence to primary caregivers that patient referrals will yield good care and ensures universal access to low-cost mammography screening facilities as well as careful record keeping with a reminder system.

Four components seem necessary to sustain the increases in screening mammography that occurred from 1987 to 1990: culturally specific public health programs to promote screening for early detection of breast cancer, greater acceptance of mammography as a breast cancer prevention strategy in the medical community, reorganization of facilities to provide low-cost screening mammography, and mandated universal coverage for mammogram services and breast physical examinations. □

The Next Generation: Poor Compliance with Risk Factor Guidelines in the Children of Parents with Premature Coronary Heart Disease

ABSTRACT

Objectives. The offspring of individuals with premature coronary heart disease are themselves at increased risk for myocardial infarction before the age of 55. Consensus panels have recommended that all such offspring undergo an evaluation of cardiovascular risk, including cholesterol testing.

Methods. To examine self-reported rates of cardiovascular risk factor assessment in this population, we conducted a telephone survey of 318 Canadian adults with premature coronary heart disease and of one offspring from 298 (94%) of the 318 families.

Results. The median age of the offspring was 20 years (range 2 to 39 y). Among the 219 late adolescent and young adult offspring, only 97 (44%) reported having had a blood cholesterol measurement during the preceding 3 years. Thirty-seven percent reported being current smokers, 31% were overweight, and 30% exercised fewer than three times per week. Men were less likely than women to report having had their blood pressure measured in the preceding year (57% vs 80%).

Conclusions. These low rates of cardiac risk factor assessment in families of patients with premature coronary heart disease represent missed opportunities for primary prevention. More effective strategies to prevent atherosclerosis in this population are needed. (*Am J Public Health.* 1994;84:68–71)

Introduction

Individuals with a history of premature coronary heart disease in one or more first-degree relatives are 2 to 13 times more likely to develop a myocardial infarction before the age of 55 than are members of the general population.[1,2] Moreover, risk factors for coronary heart disease aggregate within families,[3–7] and many offspring of individuals with premature atherosclerotic heart disease have unfavorable lipoprotein profiles.[8–11] Based on these observations, the Canadian Pediatric Society, the American Academy of Pediatrics, and consensus panels in both Canada and the United States have recommended that all offspring of parents with premature coronary heart disease undergo an evaluation of cardiovascular risk, including cholesterol or lipoprotein testing.[12–16] To assess whether these recommendations are being adopted, we surveyed Ottawa residents with premature coronary heart disease and a sample of their offspring regarding their awareness and management of cardiovascular risk factors.

Methods

Definitions

Coronary heart disease was defined as a documented myocardial infarction or at least a 50% diameter stenosis on coronary angiography, as graded visually by the angiographer. Criteria for the diagnosis of myocardial infarction were those used in the Cardiac Arrhythmia Suppression Trial.[17,18] Coronary heart disease was classified as premature if it occurred in men younger than 50 years of age or in women younger than 60.

Study Population

Patients meeting the age criteria were eligible for this study if they lived in the Ottawa metropolitan area and had either suffered a myocardial infarction or undergone coronary angiography between January 1, 1988, and February 28, 1990. We identified eligible patients from (1) the computerized records of the University of Ottawa Heart Institute catheterization laboratory, the only cardiac catheterization laboratory for adults in the city; and (2) a computerized database of patients admitted to seven regional hospitals with a new myocardial infarction (eligible participants for the Cardiac Arrhythmia Suppression Trial).

Sixty individuals had participated in the Cardiac Arrhythmia Suppression Trial and were exposed to more intensive medical surveillance than the general population of those with premature coronary heart disease. Because this could have increased the rate of risk factor assessment among both patients and their offspring, trial participants were excluded from this survey. The remaining patients screened for participation but not enrolled in the trial included 408 age-eligible patients suffering a myocardial infarction between January 1, 1988, and February 28, 1990. Of these, 73 lived outside the Ottawa region, 7 had clinically significant preexisting non-ischemic heart disease, and 77 lacked a recorded telephone number. We

attempted to contact the remaining 251 patients.

Of the 5643 diagnostic angiograms performed in the same 2-year period, 1141 patients met both age and angiographic criteria for this study. We excluded 35 who lacked a telephone and 115 who had already been identified from the Cardiac Arrhythmia Suppression Trial database. From the remaining 991, we selected a random sample of 356 patients using a computer-generated list of random numbers.

Design

Interviewers obtained verbal consent before proceeding with the telephone interview. After each adult with premature coronary heart disease was interviewed, we sought permission to contact one offspring for a similar interview. Eligible offspring were those over 2 years of age. From those eligible, we selected the individual in each family whose birthday was closest to and before the date of the parent interview. We interviewed offspring aged 16 years and older directly, and asked the parent most familiar with the child's habits to respond for children under 16. The study was approved by the Research Ethics Committee of the Ottawa Civic Hospital.

Study Instrument

The questionnaire for this study was developed using both original questions and questions previously validated in larger health surveys. The structured telephone interview consisted primarily of standardized short-answer questions on the following topics: (1) general health, (2) family history of heart disease (elicited from the parent), (3) dietary changes made in the previous year, and (4) self-reported cholesterol and blood pressure measurements.

The questionnaire was pretested for clarity, content coverage, and face validity. Eight interviewers (medical students and medical secretaries) conducted the surveys over a 12-week period beginning in July 1990. Six telephone calls at different times of the day were attempted over a 2-week period before eligible individuals were regarded as unreachable. If the index patient had died, no attempt was made to interview the offspring. We did not attempt to locate subjects whose telephone numbers were incorrectly listed on the computer database.

Sample Size Calculations

We estimated that 20% of the target group would be ineligible (lack of offspring or dead), that 20% would be unreachable, and that 10% would refuse to be interviewed. The chief outcome measure in this study was the proportion of offspring who had reported having undergone blood cholesterol testing. We estimated this proportion to be 25%. To obtain a 95% confidence interval within 5% of this figure, we determined that we would need to approach approximately 600 patients from both databases and to interview 300, using a sampling frame of one offspring per patient.

TABLE 1—Response Rates, Exclusions, and Reasons for Nonresponse in the Total Sample

	No.
Selected sample	607
Ineligible	
No children	57
Deceased[a]	16

[a]One offspring of a deceased patient was interviewed.
[b]"Wrong phone number" includes those who had moved, whose numbers were not in service, or whose numbers had been entered incorrectly into the database.
[c]"Other" includes respondent's inability to speak French or English, or parent or child being in the hospital or out of the country.

TABLE 2—Risk Factors among Parents with Premature Coronary Heart Disease (n = 318)

	No.	%
Male	204	64.2
Smokers[a]	99	31.1
Ex-smokers (all)	174	54.7
Quit < 5 years (% of ex-smokers)	125	71.8
Overweight, by BMI[b]		
25–26.9	63	19.8
≥27	172	54.1
Hypertension	116	36.5
High cholesterol	175	55.0
Family history[c]		
One relative	112	35.2
Two or more relatives	64	20.1

[a]Defined as those who had smoked at least 100 cigarettes and were still smoking.
[b]BMI = body mass index (weight/height^2).
[c]Positive family history denotes relative with heart attack before age 55.

Data Analysis

Comparisons between groups were conducted using contingency tables and chi-square statistics for categorical variables, and two-tailed *t* tests or analysis of variance for interval or continuous data. The Fisher's Exact Test was used for categorical analysis when warranted by small cell sizes.

Results

Description of the Study Population

Table 1 shows the response rates, exclusions, and reasons for nonresponse. The refusal rate among contacted eligible patients was 13% (48/367). Interviewed subjects did not differ from those who were not interviewed or not surveyed in either the prevalence of cardiovascular risk factors (smoking, diabetes, previous myocardial infarction) or angiographic measures of heart disease severity (left ventricular dysfunction, left main disease, triple vessel disease).

Table 2 shows the distribution of risk factors for coronary heart disease in this population. Fifty-two percent had three or more of these risk factors. We interviewed one offspring from 298 (94%) of the 318 families. Among the offspring, 56% were female; 10% were aged 2 to 10 years, 36% were age 10 to 19, 40% were age 20 to 29, and 14% were age 30 to 39.

Risk Factors in Offspring Older Than 16 Years

In addition to the positive family history for premature coronary heart disease, information was available on five other classic risk factors from the 219 offspring aged 16 years and older (Table 3). By these criteria, 165 (75%) had at least one additional risk factor, 88 (40%) had only one, 63 (29%) had two, and 14 (6%) had three or more. Table 4 displays comparable results for both the general population of Ottawa in 1987 and those with a family history of heart disease.

Of respondents aged 16 years and older, 78% had been examined by a physician in the preceding 3 years. Only 97 (44%) reported having had a blood cholesterol measurement performed during those 3 years, and just 5 of these 97 actu-

Source. Data accessed with permission of Dr G. Dunkley.
[a]Respondents were 19 to 39 years of age. Thus, for the Heart Beat Survey, n = 679; for the current survey, n = 178.
[b]FH CHD = Family history of coronary heart disease (yes = 279, no = 400), as defined by the response to the question: "Has anyone in your immediate family had heart problems?"
[c]Correspond to chi-square values, which represent a 3 × 2 comparison based on the three data columns.

ally knew their cholesterol levels. Offspring were more likely to have had a cholesterol measurement performed if they were at least 25 years of age (60% vs 42%; $P < .01$) and if they had undergone a physical examination within the past year (59% vs 36%; $P = .001$).

Knowledge of Risk Factors

When asked to list the major causes of heart disease or heart attacks, respondents most frequently cited dietary factors (mentioned by 99%), smoking (58%), stress (57%), lack of exercise (21%), and high blood pressure (9%). Only 13% identified heredity as an important factor. Current smokers were more likely to rate smoking as a cause of heart attacks than were nonsmokers (72% vs 59%; $P < .01$).

Changes in Risk Factors

Among offspring at least 16 years of age, 67% (60% of men and 72% of women) reported having changed their diet in the preceding 2 years to reduce their risk of heart disease. Univariate analyses showed no clinically or statistically significant difference between those who did and did not change their diets with regard to age, education, marital status, smoking status, body mass index, physical exam within the previous year, or blood pressure measurement within the previous year. Only the level of worry about future heart disease was significantly related to dietary change. Of those who had a below-average worry rating, only 52% had changed their diets, compared with 76% of those who worried more ($\chi^2 = 13.5$, $P = .001$). Smokers were almost three times as likely as nonsmokers to report having made no efforts to improve their health in the preceding year (30% vs 11%, $P = .001$). Those with two risk factors for coronary heart disease besides family history were marginally less likely to have made changes in diet in the preceding year than were those who had no other risk factors (77% vs 91%, $P < .04$).

Offspring Younger Than Age 16 Years

More limited information was available regarding the remaining 79 offspring aged 2 to 16 years. Nine parents provided proxy responses for their 16-year-old children; we analyzed data for these adolescents with the younger offspring. Fifty-five children (70%) had seen a physician in the preceding year. Sixteen parents (20%) reported that the child had undergone a cholesterol measurement at some time. Forty-four parents (56%) were aware of a measurement of the child's blood pressure in the preceding year.

Discussion

This survey of the offspring of Canadian adults with premature coronary heart disease has identified a low rate of compliance with current guidelines for the prevention of atherosclerosis.[12,13] Only 38% (113/298) of the offspring reported being aware that they had undergone cholesterol testing in the preceding 3 years, and only 57% of those aged 16 and over reported having had their blood pressure measured in the preceding year. Many of the late adolescent and young adult offspring also reported being smokers, being overweight, and exercising less often than three times per week. That 37% were current smokers is of particular concern in light of evidence that smoking multiplies the risk of ischemic heart disease in those with a positive family history.[19,20]

These data show that the current case-finding approach to identifying and screening high-risk offspring is ineffective. Although the reasons for this are complex, we identified a lack of awareness of the increased risk posed by a positive family history, as has been reported in studies of siblings of adults with coronary heart disease.[5] While it is true that the offspring in our survey were not asked to rate the relative importance of family history as a contributor to the development of heart disease, only 13% of the older offspring mentioned heredity as a major cause. Moreover, only 55% of the parents with premature coronary heart disease reported premature myocardial infarction among their close relatives. It thus appears that this increased risk has received insufficient attention over two generations, and that the attitudes and behaviors of the parents regarding cardiovascular risk are shared by their children.

A comparison of the present survey with the 1987 Ottawa Carleton Heart Beat Survey suggests that recommendations for the primary prevention of premature coronary heart disease are being adopted at a slow pace, as has been observed in the United States.[21] Compared with findings from the Heart Beat Survey, we found substantially higher rates of cholesterol screening. Although this difference may reflect more intensive screening of family members than of others in the population, as was recommended in Canada in 1989,[22] it is also possible that more people in 1990 were having cholesterol screening regardless of family history.

We cannot attribute the low rates of cardiovascular risk assessment identified in this study to a lack of public health information about the link between elevated cholesterol levels and heart disease. During the decade before this survey, residents of Ottawa were exposed to local heart health campaigns as well as to intense national and US media coverage of this issue. Unlike the United States at present, there are no financial barriers to medical examination and lipoprotein measurement in the Canadian health care system. However, there may be disincentives in both countries to identifying and providing preventive care to those with a history of premature coronary heart disease among first-degree relatives. To function well, the present system demands one of two things: either an exemplary effort by practitioners to schedule assessments of offspring (some of whom may not be members of the physician's practice) once premature coronary heart disease is recognized in a parent; or an unusually high level of knowledge among offspring about the risk associated with their family history, which then leads them to request an appointment. An alternative to the current method would be a structured program of education, risk factor assessment, and intervention, which would be offered to family members of patients presenting with premature coronary heart disease. Before such a program could be implemented, however, it would have to be demonstrated that the preventive strategy leads to the desired changes in behavior without adding an unhealthy psychological burden to the offspring identified as being at increased risk. □

"Eat For Health": A Supermarket Intervention for Nutrition and Cancer Risk Reduction

ABSTRACT

Objectives. The results of an evaluation of "Eat for Health," a supermarket nutrition intervention, are presented. The study tested whether such a program could be successfully carried out and whether it could effect changes in knowledge, attitudes, and food purchasing behavior in line with nutrition and cancer risk reduction guidelines.

Methods. The evaluation consisted of an in-store monitoring element, an in-store and telephone consumer survey, and an analysis of sales data on selected foods. A matched-pair design, using a total of 40 stores in the intervention and comparison groups, was used.

Results. The intervention was successfully implemented and had limited success in changing some food purchasing behaviors. There appeared to be no effect on knowledge and attitudes except for increased awareness of a link between diet and cancer and of the program itself.

Conclusions. Despite the intervention's success, limitations of the consumer survey and sales data analyses and the continuing diffusion of nutrition messages throughout society make it difficult to specify the impact of this program on consumer nutrition knowledge and behaviors. (*Am J Public Health.* 1994;84:72–76)

Introduction

Since the 1970s, a variety of programs have been implemented to test the proposition that information provided in supermarkets not only can increase awareness and knowledge of healthful food choices but can provide specific, focused guidance in making those choices. Evaluations of the few programs with evaluation components have shown mixed results, with some improvement in knowledge and attitudes and modest, if any, changes in behavior.[1–13]

In March 1987, the National Cancer Institute (NCI), one of the National Institutes of Health, launched a 2-year multicomponent supermarket intervention in cooperation with Giant Food Inc, a major supermarket chain in the Washington, DC–Baltimore, Md, area. The "Eat for Health" program was intended to stimulate changes in knowledge and food purchasing behavior consistent with NCI's dietary recommendations for cancer risk reduction. These recommendations focus on reducing fat intake and increasing consumption of fruit, vegetables, and other fiber-containing foods.[14] The intervention was conducted in Giant's 105 Washington-area stores, while its 30 Baltimore stores served as the comparison group. Program elements included special shelf price labels; a food guide containing calorie, fat, cholesterol, sodium, and fiber values for all items carrying the special shelf price labels; a monthly bulletin containing nutrition information and recipes; signs in the produce department; and an intensive multimedia advertising campaign. Individual 3-month interventions, which were evaluated separately, were developed during the second year of the campaign in conjunction with the National Livestock and Meat Board and several poultry producers. The components and development of Eat for Health are described more fully in Light et al.[15]

The Eat for Health study was evaluated to (1) assess participating stores' ability to implement this multimethod nutrition education program; (2) measure changes in consumer purchases of fiber-rich and lower-fat foods; and (3) assess changes in consumer knowledge about diet and health issues, specifically diet and cancer issues, and self-reported food purchasing and preparation.

Methods

The Eat for Health evaluation consisted of an in-store monitoring program, an in-store and telephone consumer survey, and an analysis of sales data on selected foods.

A matched-pair design was selected, using 20 stores in the intervention group and 20 stores in the comparison group. Data from the 1980 US Bureau of the Cen-

sus decennial survey were used to match stores with regard to their neighborhoods' racial composition, age distribution, occupation, income, and proportion of homeowners. Stores were also matched with regard to volume and presence or absence of a pharmacy.

In-Store Monitoring

The Eat for Health monitoring component consisted of nine visits to the 20 intervention stores selected for evaluation. In these visits an NCI staff person talked with the store manager and checked on availability of program materials. This component was based on experience from previous supermarket interventions that showed the importance of the availability of program materials and a commitment to the program by supermarket managers and staff.[7,9] Odenkirchen et al. have described the monitoring program in more detail.[16]

Consumer Surveys

This series of three surveys was administered to shoppers from the 20 matched pairs of Washington and Baltimore stores selected for evaluation. Wave 1 was a baseline survey conducted in February and March 1987, wave 2 was conducted in January, February, and March 1988, and wave 3 was conducted in February, March, and April 1989. The shortened version of the food frequency portion of NCI's Health Habits and History Questionnaire was adapted for mail and self-reported administration.[17]

Potential survey participants were included only if they did more than 50% of the household shopping and shopped at Giant more than 50% of the time; ate less than 50% of their meals outside the home; were between the ages of 21 and 75 years; had no medical condition requiring a special diet; and did not work in the food, health, or market research industries. Table 1 provides further detail on response rates.

To evaluate responses to the three cross-sectional surveys, an analysis of covariance approach was adopted in which the survey wave (1, 2, or 3) and place (Washington vs Baltimore) served as main effects and the survey response items served as the dependent variables in a series of ordinary least squares multiple regression models.

Sales Data

Summary sales data were obtained each week from Giant's computerized cash registers, which record purchases by Universal Product Code. Data were collected for 1 baseline year (March 1986 through February 1987) and the 2 intervention years (March 1987 through March 1989) in the same 20 matched pairs of stores used for the monitoring and consumer surveys. The analysis of sales data focused on changes in purchases of fiber-containing foods, although sales data for meat and poultry were analyzed as well. A cross-sectional time series regression procedure was used to analyze the data.

Eight mutually exclusive food categories were targeted for analysis: dry cereal, baked goods, fresh produce, frozen vegetables, canned vegetables, canned and frozen beans, dried beans, and dried fruit.

Foods in each of the eight categories tracked for analysis were grouped into two subcategories: "recommended" and "other than recommended." Recommended foods contained at least 2 g of fiber and less than 30% of calories from fat. All other foods in each category were other than recommended.

The effect of the Eat for Health intervention was measured by two variables. The first was "recommended ounces," or sales in ounces of recommended food items in each category. The second was "percent recommended," or the percentage of all the foods sold in each category that were in the recommended subcategory. This portion of the evaluation is described in Patterson et al.[18]

TABLE 1—Number of People Responding and Response Rate at Each State of Data Collection, by Wave

Response Category	Wave 1	Wave 2	Wave 3
A. Total approached	3084	3268	3218
B. Initially refused (would not speak to interviewer)	729	641	973
C. Refused (qualified but would not participate)	170	166	112
D. Disqualified	682	1141	734
E. Qualified and participated [A – (B+C+D)]	1503	1320	1399
F. Response rate, % (E/A – D)	62.6	62.1	56.3
G. Completed questionnaire	958	1045	1031
H. Response rate, % (G/E)	63.7	79.2	73.7
I. Completed telephone interview	917	1019	1042
J. Completed questionnaire and telephone interview	917	957	893
K. Response rate, % (J/G)	95.7	91.6	86.6

Results

In-Store Monitoring

At the start of the Eat for Health program, it was determined that project elements (shelf labels, food guides, produce signs, and monthly bulletins) complied with the research protocol if they were available and located properly and if the nutrition information on the shelf labels was correct. The goal for project elements was an average compliance rate of 80%.

Not surprisingly, the shelf labels had the highest compliance rate, averaging 92% to 100% over the program. This high compliance rate was largely due to the fact that the labels were computer-generated and therefore uniform and up-to-date in content. Also, once attached to the shelf the labels did not move.

The *Eat for Health Food Guide* also had a high compliance rate, with booklets available at an average of 85.3% of all checkouts. Like the shelf label, this element was stable; once placed in a rack at the checkout counter, the booklets were not moved and only had to be replaced as copies were sold.

The produce signs also met the project goal, with an average compliance rate of 83.2%. This average was considered particularly good, as the signs were frequently moved and changed when items in the produce department were shifted.

The Eat for Health monthly bulletin had the lowest compliance rate over the monitoring periods, averaging 63.5% for operating checkouts. Compliance differed most significantly from store to store, with a range of 31.6% to 89.5% at operating checkouts. This lower compliance rate was of some concern because the free take-home bulletin was the only element of the program that contained detailed information on Eat for Health issues. One possible reason may have been the bulletin's popularity. It was often out of stock by midmonth. Another reason may have been its location at the end of the checkout, a busy place that is crowded with materials such as grocery bags and other store flyers. Despite this disadvantage, previous programs had demonstrated that

TABLE 2—Results for the Five Hypotheses Developed from the Overall Objectives of the Eat for Health Consumer Surveys

General Message/Questions	Survey Items	Adjusted Percentage Difference[a] Consumption	Purchase	Comment
	Hypothesis 1			
Choose more high-fiber foods	Vegetables	1.2	3.8	No statistically significant effect except for beans; insufficient to confirm hypothesis.
	Fruit	0.6	−2.0	
	Whole grains	−1.5	0.9	
	Beans	0.5	8.3*	
	Potatoes	−0.5	5.6	
Choose less high-fat foods	Bakery/snacks	−1.1	−8.9*	Trend favors positive program effect, but insufficient to confirm hypothesis.
	Whole milk prod.	−0.9	−4.4	
	High-fat foods	−4.2*	−1.4	
	Fried food	−0.8	...	
	Fats/oils	−1.1	...	
Choose more low-fat foods	Low-fat/skim milk	−1.1	3.1	Trend favors positive program effect, but insufficient to confirm hypothesis.
	Poultry	0.4	7.6	
	Fish	−0.1	−2.2	
	Hypothesis 2			
Use more low-fat cooking methods	Baking	0.0		Insufficient evidence to confirm hypothesis.
	Broiling	8.6		
	Boiling	−2.2		
	Steaming	3.6		
	Microwaving	−3.5		
	Pressure-cooking	2.7		
Fry less; eat less charred/barbecued meats	Frying	−4.7		
	Stir-frying	−9.2*		
	Sautéing	−4.9		
	Grilling/barbecuing	−3.0		
	Hypothesis 3			
Food items that reduce cancer risk?	Fiber	3.8		Overall trend favors positive effect, although insufficient to confirm hypothesis.
	Fresh fruit	15.7*		
	Vegetables	2.2		
	Whole grains	−2.8		
	Fish/poultry	3.8		
Food items that increase cancer risk?	Dairy products	0.7		
	Fatty foods	−6.3		
	Fatty meats	8.9		
	Hypothesis 4			
Is diet related to cancer?	Unprobed	14.2*		Hypothesis well supported by results.
	Direct questions	5.4		
Is diet related to other chronic diseases?	Heart disease	−3.0		
	Obesity	6.1*		
	Diabetes	3.1		
	Hypothesis 5			
Heard of Eat for Health?	Via mass media	18.8*		Hypothesis well supported by results.
	In store	3.2		
Heard of special promotion?	Via mass media	0.1		
	In store	10.4*		
Heard of fiber?	Via mass media	8.4*		
	In store	17.0*		
Store provides nutrition information?		19.3*		
Shelf labels provide nutrition information?		11.4*		

[a]Difference between Washington and Baltimore in change from wave 1 to wave 3, controlling for 12 sociodemographic and health-related variables.
*$P < .05$.

the checkout was the best possible location for the bulletins.

Consumer Surveys

It was hoped that the five research hypotheses that were developed from the surveys would provide substantial insight into the dynamics of nutrition knowledge and practices in the Washington and Baltimore communities and would demonstrate an effect of the intervention materials on food purchasing and consumption behavior. These hopes were not entirely realized, as only two of the hypotheses were supported by the data. Table 2 summarizes the results for the five hypotheses.

Hypothesis 1. Self-reported purchasing and consumption of foods high in fiber and low in fat would increase, and purchasing and consumption of foods high in fat would decrease.

The analysis showed no statistically significant effect on self-reported purchases of high-fiber foods, with the exception of dried beans. In contrast, the direction of differences from wave 1 to wave 3 appeared to show a program effect for choosing fewer high-fat foods. However, the majority of differences were small and the results were not sufficient to confirm the hypothesis.

Hypothesis 2. There would be changes in food preparation methods consistent with the Eat for Health recommendations.

The only consistent trends that appeared here were for less frying and use of barbecued food, but these trends were not statistically significant.

Hypothesis 3. There would be an increase in knowledge about foods related to cancer risk reduction.

Although an overall pattern favoring a positive effect was apparent, it was not strong enough to confirm the hypothesis.

Hypothesis 4. There would be an increased awareness of the relationship between diet and chronic disease.

It appears that Eat for Health's diet and cancer message made a clear impression on Washington shoppers. The proportion of these shoppers who mentioned, unprompted, a link between diet and cancer increased by 14.2 percentage points over the Baltimore figure from wave 1 to wave 3. This was a large and significant change.

Hypothesis 5. Awareness of the Eat for Health program would increase.

This hypothesis was also well supported by the results. Significantly more Washington shoppers than Baltimore shoppers heard of Eat for Health over

time. In particular, awareness of fiber information and awareness of the supermarket as a source of nutrition information favored a positive program effect.

Sales Data

Dry cereals. The dry cereal category included all dry cereals sold by Giant. The recommended subcategory included all high-fiber cereals. Sales data showed a striking decline in sales of these cereals. After price and other confounding variables were taken into account, the data showed a greater decrease in sales of recommended cereals in Washington than in Baltimore, indicating a negative intervention effect.

Baked goods. The baked goods category included all types of breads and rolls. Recommended types included whole wheat, natural grain, and bran-type breads. In both intervention years, the number of recommended ounces was greater than in the baseline year, but intervention effects were negative. This indicated that shoppers in both areas bought more of the recommended breads, but the trend was stronger in Baltimore than in Washington.

Fresh produce. The fresh produce category included a wide variety of fresh fruits and vegetables available in Giant supermarkets. The number of recommended ounces sold decreased in Baltimore during the intervention period compared with the baseline year. In Washington, on the other hand, sales of recommended ounces increased over the course of the intervention. During the second year, adjusted sales increased almost 8% more in Washington than in Baltimore, a result that approached statistical significance. An increase in percentage of recommended sales over baseline was also seen in both years in Washington, compared with only year 1 in Baltimore. After adjustment, Washington showed a statistically significant relative increase in market share over Baltimore (2.4%) during the intervention period.

Frozen vegetables. The frozen vegetable category included most types of frozen vegetables; more than 60% of sales were in the recommended subcategory. Average sales changed little over the study period, although there was a small decline in percentage of recommended items sold. The decline in sales of recommended frozen vegetables was significantly smaller in Washington than in Baltimore, indicating a positive intervention effect.

Canned vegetables. The canned vegetable category included all canned vegetables. The recommended subcategory included corn, green peas, and lima beans. The number of ounces of vegetables in the recommended category fell during both study years compared with the baseline period, but the decline was greater in Baltimore than in Washington, resulting in a statistically significant increase in sales of the higher-fiber vegetables recommended by Eat for Health.

Canned and frozen beans. The canned and frozen bean category included baked and other canned beans and frozen beans, such as kidney beans and black-eyed peas; all items in this category were recommended. Intervention effects were negative but not statistically significant.

Dried beans. All types of dried beans were included in the dried bean category, and practically all were in the recommended subcategory. Sales declined from baseline in both areas, but again, the decline was smaller in Washington than in Baltimore, and positive intervention effects were seen for both intervention years. These changes approached statistical significance.

Dried fruit. The dried fruit category included raisins, dates, and other types of dried fruit; all were in the recommended subcategory. Results for this category were similar to those for dried beans in that intervention effects were positive but did not reach statistical significance.

Meat and poultry. The results of the separate analyses of the second-year meat and poultry interventions reveal limited changes, primarily associated with price, in the purchase of recommended vs other than recommended types during each 3-month intervention period related to the previous 1-year period. For meat, mean recommended ounces and percent recommended ounces decreased in both Baltimore and Washington; the decrease was smaller in Washington. For poultry, recommended ounces increased in both areas, but more so in Washington.

Discussion

Three goals were set for the Eat for Health program: (1) to demonstrate that a multifaceted nutrition information program could be carried out in more than 100 supermarkets over a period of 2 years; (2) to effect changes in food purchasing behavior in line with NCI's nutrition and cancer risk reduction dietary guidelines; and (3) to stimulate positive changes in knowledge and attitudes toward diet and health issues. Judged against these goals, Eat for Health had mixed success.

The ability to carry out such a large-scale, long-term program was strongly demonstrated. Over its 2-year span, from 150 000 to 200 000 bulletins were distributed each month for 25 months, more than 100 000 food guides were sold, and hundreds of thousands of people were exposed to a multimedia advertising campaign. Numerous groups and individuals were cooperatively involved in the preparation, review, and implementation of the many project elements. In the course of developing the program, Eat for Health staff were conscious of elements of previous supermarket interventions that had contributed to their successful implementation.[1,2,6,7,9] A number of these were found to work well for Eat for Health also. Important among them was the good working relationship between the Eat for Health program staffs at NCI and Giant Food. This relationship was formalized by an agreement outlining roles and responsibilities of both collaborators and further enhanced by the continual support of senior management at Giant and NCI. Training of Giant store managers and other staff and open discussion between store managers and the NCI staff person during monitoring visits also stimulated commitment to the program.

With respect to the second goal, Eat for Health's effect on food purchasing behavior appears to have been modest. This conclusion recognizes several limitations imposed by the complexity of the technical problems inherent in the analyses and by the realities of conducting research in a marketplace setting.

Because the intervention and control groups had to be assigned to Washington and Baltimore groups of stores rather than on a random basis, it was difficult to ensure comparability of the two groups and therefore to determine whether changes in sales were due to the intervention rather than to inherent differences in the study groups. Very large fluctuations in the levels of sales also occurred during the course of the intervention, resulting in tremendous variability in the data, which made it difficult to detect any intervention effect.

Despite these limitations, some changes in food purchasing behavior were observed, particularly with respect to produce. This may have been due to the emphasis on fruits and vegetables in the monthly bulletins and produce signs, to the popular weekly half-price sales in which the Giant salad bar was often fea-

tured, and to a public perception of the superiority of fresh produce.

Results in the third area—nutrition knowledge and attitudes and self-reported food purchasing behavior—appear to have been the most modest. Several possible reasons for this slight effect can be suggested. Washington-area shoppers may have already been sensitized to the general diet and health messages of Eat for Health by the two previous nutrition interventions held in Giant Food stores (Foods for Health in 1979 and Special Diet Alert in 1981) and by Giant's well-known commitment to providing nutrition information in its stores even in the absence of a formal intervention. National public health and private sector media campaigns related to various food and health issues may also have previously affected the knowledge and behaviors of Washington-area consumers. Finally, intervention stores happened to be located in more affluent areas than were comparison stores, and this somewhat higher socioeconomic status may account in part for the greater awareness of Washington shoppers. It should be noted, however, that the greatest positive change occurred for knowledge of a relationship between diet and cancer. This was a relatively new piece of information for consumers and the fact that such a dramatic change occurred here argues in favor of the effectiveness of Eat for Health materials in transmitting concepts to consumers.

Like the sales data, these survey data were analyzed in light of several recognized concerns and limitations. First, there was concern about the reliability of consumer responses to nutrition surveys. In particular, we were sensitive to the experience of previous programs, such as the Special Diet Alert and the Lean Meats Make the Grade programs, in which survey respondents claimed awareness of the program even before its inception or demonstrated confusion between the program and other types of nutrition promotions in the store.[2,6] To some extent this was true for Eat for Health as well, although knowledge of Eat for Health per se increased dramatically over the study period. Second, as this was a quasi-experimental study, there was very little control over survey participants' shopping behavior and media access, and therefore the sample of shoppers for the survey may not have been truly representative. Third, the time frame for data collection in the first wave was unexpectedly delayed, and data collection was still ongoing for several days after the program was launched.

Conclusions

One way to encourage and strengthen positive behavior change is to institutionalize its catalysts. Providing appealing, usable information in the supermarket that complements the healthful choices available there is one example of this process. Supermarket programs have demonstrated their value in enhancing customers' satisfaction with and loyalty toward their stores.[19,20] As a result, nutrition programs appear to be an entrenched feature of the supermarket business landscape.[21,22]

As messages and support systems for healthful dietary change become more established in the marketplace and diffused throughout society, it may be increasingly difficult to detect an impact from any one supermarket intervention. On the other hand, the positive contributions of these programs—along with those of many other nutrition efforts—may be reflected over time in the gradual lowering of nutrition-related chronic disease rates. □

A Workplace Intervention for Increasing Outdoor Workers' Use of Solar Protection

Afaf Girgis, PhD, Rob W. Sanson-Fisher, PhD, and Alan Watson, MBBS, DDM

ABSTRACT

Objectives. Outdoor workers are at high risk of developing skin cancer. Primary prevention in this group can potentially reduce the incidence of skin cancer, and also potentiates the spontaneous remission of existing solar keratoses. A randomized controlled trial was conducted to evaluate a solar protection intervention targeting outdoor workers.

Methods. Outdoor workers were randomly allocated to an intervention (n = 65) or control group (n = 77). The intervention group received individual skin screening by a dermatologist and participated in an education session. Pre- and posttest outcome measures included solar protection behavior (assessed using a validated diary), knowledge, and attitudes.

Results. There was a significant increase (16%) in the percentage of outdoor workers who were using a high level of solar protection at posttest compared to pretest in the intervention group, but there was no change in the control group. Although both groups improved in their knowledge score, the intervention group showed a significantly greater improvement at posttest. No changes in attitudes were detected.

Conclusions. The findings suggest that changes in solar protection are achievable with outdoor workers. (*Am J Public Health.* 1994;84:77–81)

Introduction

Skin cancer is the most common form of cancer affecting Australians,[1] and Australia has the highest incidence of skin cancer in the world.[2] In 1987, 20 to 25 Australians per 100 000 were diagnosed as having cutaneous malignant melanoma,[3] and 823 Australians per 100 000 were diagnosed as having nonmelanocytic skin cancers.[4] In Australia, skin cancer results in 1000 deaths each year and has been estimated to cost the community $400 million annually.[5]

Although the burden of illness associated with skin cancer is significant, this disease is estimated to be almost 80% preventable[6] and almost 100% curable by the adoption of a correct and vigilant set of primary and secondary preventive behaviors.[7,8] Primary preventive behaviors, which limit exposure to ultraviolet radiation, not only offer the best prospect of reducing the incidence of skin cancer,[6,9] but also potentiate the spontaneous remission of existing solar keratoses[10] prior to possible malignant transformations.[11] A substantial reduction in the number of solar keratoses has been observed in outdoor workers who were able to reduce their sunlight exposure over a 12-month period.[10] Secondary preventive behaviors, or screening for skin cancers and seeking prompt medical advice, substantially improve the prognosis of existing carcinomas.[12]

There are particular groups, most notably outdoor workers, who are at increased risk of developing skin cancer, given their solar exposure. The work environment for this group intrinsically constitutes a health hazard,[12–14] and it has been found that those working in outdoor occupations are more susceptible to developing nonmelanocytic skin cancers.[15–18] Squamous-cell carcinomas and basal-cell carcinomas are reportedly almost twice as prevalent in long-term outdoor workers than in indoor workers, and outdoor workers are reportedly more than twice as likely to develop solar keratoses.[18] Outdoor workers are also more likely to develop malignant melanomas on parts of their body exposed to sunlight during working hours.[17,19,20] Hence, outdoor workers represent an important target group at risk of developing skin cancer.

While avoidance of sunlight exposure is the ideal,[6,9] such a prevention strategy cannot be exclusively incorporated into the work practices of outdoor employees. This population might, however, beneficially adopt several other primary protective initiatives, such as job planning for maximum utilization of shade areas, particularly around midday, and use of solar protection items such as protective clothing, broad-brimmed hats, sunscreens, and sunglasses. Along with such measures, which are supported by the Australian Council of Trade Unions Occupational Health and Safety Unit,[21] educational and behavioral interventions promoting the adoption of solar protection behaviors are also valued.

Note. Although this research was undertaken by the New South Wales Cancer Council Cancer Education Research Project Team, the views expressed here are the authors' and not necessarily those of the Cancer Council.

The aim of the present study is to evaluate the effectiveness of a workplace intervention in changing the knowledge, attitudes, and solar protection behaviors of outdoor workers, using a randomized, controlled trial design.

Methods

Procedure and Sample

This study involved outdoor workers from a local electrical supply authority employing approximately 1200 individuals in total. The types of tasks undertaken by these workers, which were generally performed in groups of two to five individuals, included digging trenches; lopping trees; erecting, treating, and maintaining electricity poles; and reading meters door to door.

In this randomized controlled trial, 12 depots containing outdoor workers were randomly allocated to a control or intervention group based on geographic location. This randomization procedure was used to minimize the risk of contamination between the two study groups. Employees were considered ineligible if they spent less than 80% of their day working outside or if they were going to be on leave during the study period. Following random allocation to groups, eligible employees were sent a letter from the chief investigator inviting them to participate in the research.

The effectiveness of the intervention was assessed by comparing pre- and posttest and between-group differences in solar protection behavior, knowledge, and attitudes. The pretest assessment of these variables was made in both groups during the week prior to the intervention. Following pretest measures, the intervention group participated in the intervention, which was conducted over a 1-week period. The posttest measures were collected 1 month following the completion of the pretest data. At pre- and posttest assessments, participants were asked to return their completed measures to the research team in sealed, prepaid, addressed envelopes to ensure confidentiality of information.

Pre- and Posttest Measures

Solar protection behavior diary. Consenting participants were required to complete a solar protection behavior diary for 5 consecutive working days. This diary was developed to gather self-report information about the prevailing weather conditions and about participants' clothing and sunscreen use on different parts of the body. This information allowed a protection score to be calculated for each participant for the 5-day period. The format of the diary was easy to follow, with responses being recorded by circling one of a number of options in each category. To encourage accurate recall, the diary for each day was divided into four 2-hour blocks of time between 7:00 AM and 3:00 PM, and participants were asked to complete each entry as soon as possible after the end of the 2-hour period rather than at the end of the day.

During the pretest phase, the accuracy of self-report by the target group was assessed by direct observation procedures. Both a member of the research team and a safety officer directly observed a proportion of the outdoor workers and completed the items in the diary corresponding to one of the 2-hour time periods. Kappa was used to assess the extent of agreement between the participants' responses and those made by direct observations, with significant kappa achieved in four of the five categories of interest: what was worn on the head ($\kappa = 0.71$, $P < .05$), on the face ($\kappa = 0.42$, $P < .05$), on the shoulders and arms ($\kappa = 0.64$, $P < .05$), and on the legs ($\kappa = 0.89$, $P < .05$). The only category in which disagreement was reported was what was worn on the feet, and this involved reporting whether long or short socks were worn with safety boots ($\kappa = -0.02$, $P > .05$). This difference had no bearing on the calculation of the final protection score. These results, therefore, indicate that the self-report solar protection behavior diary is a valid measure of solar protection behaviors in this target population.

Knowledge and attitudes. A questionnaire developed and previously pilot tested by the research team[22] was used in this study: part 1 comprised 6 items designed to gather information about the subjects' skin type and skin-checking behavior; part 2 consisted of 18 items that assessed knowledge about solar protection and skin cancer issues (maximum score = 23 points, including subitems); and part 3 consisted of 25 items designed to assess attitudes about solar protection and skin cancer. Responses to all items in the questionnaire were recorded by circling the appropriate response options. Details of age and gender were also obtained in the questionnaire, which demonstrated high levels of face and content validity.[23]

Principal components analysis using the statistical package BMDP, program P4M,[24] was used to identify factors from the 25 attitude items. Six subscales were extracted in this analysis, which together accounted for 41.1% of the variance. The four subscales that were internally consistent (Cronbach's alpha > .05[25]) measured participants' attitudes about their personal susceptibility to developing skin cancer (12.8%), risk-taking propensity (8%), perceived benefits of having a suntan (4.8%), and external locus of control (4.6%).

Intervention

The intervention consisted of two components: a skin screening session and an education session.

In the screening session, each participant had his or her skin individually checked by one of five practicing dermatologists. All screening was conducted in privacy, and the dermatologists were asked to rate the condition of the skin on two scales: a 7-point photodamage scale and an 8-point premalignant and malignant damage scale (Table 1). These scales were developed by the dermatologists and specialist surgeons for use in this study, based on evidence that accumulated sun damage to the skin is associated with the development of nonmelanocytic skin cancer.[17,26,27] Before the intervention was begun, a number of meetings were held to discuss the two skin scales and the extent and type of feedback to be given to the subjects. This was done to maximize the consistency among the five dermatologists in their assessment of sun damage and personal risk of the subjects. The dermatologists then informed each participant of his or her current level of skin damage and personal risk of developing more extensive damage and/or skin cancer. Where necessary, the dermatologists also advised the subjects to see their personal general practitioner for management of a lesion or for referral to a specialist for management.

In the education session, the New South Wales Cancer Council's Hunter Region education officer delivered a 30-minute lecture to the participants in groups of approximately 10 to 15 participants. The talk addressed skin cancer in Australia, the increased risk for outdoor workers, and the opportunities for prevention using both measures that are generally available and measures that are specifically issued in this workplace, such as sunglasses, wide-brimmed hats, wide brims and back-flaps for hard hats, sunscreens, long-sleeved shirts, and lightweight overalls. Participants were encouraged to ask questions, and pamphlets

supporting the lecture were also distributed.

Participants in the control group were offered the opportunity to take part in the screening and education intervention at the end of the posttest data collection.

Results

Study Sample

Of the initial sample of 127 employees in the intervention group, 14 were not eligible for participation in the study, 17 did not return any of the pretest data, and 10 completed only part of the pretest, leaving 86 employees with complete pretest data. A complete data set suitable for analysis of all variables was available for 65 (76%) of these individuals (64 men, 1 woman; mean age = 40.6 years, range = 22 to 63 years).

Of the initial sample of 136 outdoor employees in the control group, 5 were not eligible for participation in the study, 20 did not return any of the pretest data, and 13 completed only part of the pretest data, leaving 98 employees with complete pretest data. A complete data set suitable for analysis of all variables was available for 77 (79%) of these individuals (all men; mean age = 40.4 years, range = 23 to 61 years).

Analyses were conducted to assess whether there were any differences in baseline variables between participants who had completed only part of the study (e.g., pretest data only) versus those who had completed all parts. These comparisons revealed no significant differences in age ($P = .124$), baseline knowledge ($P = .395$), and baseline solar protection score ($P = .149$).

Photodamage and Premalignant and Malignant Damage

A test for trend was conducted on the control and intervention groups' results and indicated that the two groups did not differ from the linear trend on either the photodamage scale ($P = .444$) or the premalignant and malignant damage scale ($P = .571$). Given the small sample in a number of the cells, grades 4 to 6 were collapsed in the photodamage scale and grades 3 to 7 were collapsed in the premalignant and malignant damage scale, prior to conducting the test for trend. The proportions of outdoor workers with different levels of damage on the two scales are presented in Table 1. The two scales were found to be significantly correlated ($r = 0.57$, $P = .0001$), indicating a positive relationship between the degree of photodamage and premalignant/malignant change in the skin.

TABLE 1—Proportion of Outdoor Workers with Different Grades of Photodamage and of Premalignant and Malignant Damage to Skin

Grade of Damage	Outdoor Workers, %	
	Intervention Group (n = 86)	Control Group (n = 98)
Photodamage		
0 None	7.48	2.91
1 Minimal macular hyperpigmentation and fine wrinkling	22.43	18.45
2 Pigmentary changes more marked in association with mild yellowing and thickening and mild coarse wrinkling	31.78	39.81
3 Both hyper- and hypopigmentation with moderate degree of yellowing, coarse wrinkling, and fine wrinkling in one area	15.89	14.56
4 Involvements of more than one area to a grade of 3	16.82	23.30
5 Severe pigmentary change, laxity, fine and coarse wrinkling in one area	1.87	0.00
6 Changes of grade 5 in all areas	3.74	0.97
Premalignant and malignant damage		
0 None	42.99	30.10
1 Presence (or history of previous treatment) of solar keratoses in one area only	26.17	31.07
2 Presence (or history of previous treatment) of solar keratoses in two areas	16.82	21.36
3 BCCs but no solar keratoses	0.00	0.00
4 Presence (or history of previous treatment) of BCCs or SCCs as well as of solar keratoses	11.21	16.50
5 Severe dysplastic change (to include solar keratoses, BCCs, SCCs, or Bowen's disease) in one area	1.87	0.97
6 Total dysplastic change in one area	0.00	0.00
7 Total dysplastic change in all areas	0.00	0.00

Note. BCC = basal-cell carcinoma; SCC = squamous-cell carcinoma.

Solar Protection Behavior

A protection score was calculated for every opportunity available for protection. An opportunity was defined as the worker's being outdoors between 11:00 AM and 3:00 PM when there was no rain. Protection level was calculated by giving each participant an aggregate score for the use of solar protection measures on each of nine body regions. A body region was considered to be adequately protected if it was fully covered by clothing/hat or shaded at the time of the interview, and/or if sunscreen lotion with a sun protection factor of 15 or higher had been applied to that region, as recommended by Australian Cancer Councils.

The points assigned to each body region were weighted to reflect the comparative risk, as indicated in the literature, of that region developing melanoma or skin cancer.[13,28-30] Thus, the face, back, and legs were appointed a maximum protection score of 3 points each, the shoulders and upper arms were appointed a maximum protection score of 2 points each, and the remaining body areas (neck, lower arms, chest, and stomach) were appointed a maximum protection score of 1 point each. Using this relative weighting scale, participants' overall protection level was scored out of a possible maximum of 17 points. Participants who scored 13 or more points (>75% of the body protected) were classified as having high protection during the period of diary completion. This cutoff point was selected to ensure consistency with previous research.[31]

Using this definition, z scores[32] used to make between-group comparisons indicated no baseline difference between the two groups in the percentage of workers protected (intervention = 50%, control = 49%; $P = .904$) but a significant difference at posttest (intervention = 66%, control = 49%; $P = .042$), with a greater proportion of outdoor workers in the intervention group having high solar protection. McNemar's test[32] was used to assess the change in protection from pretest to posttest in each group. As Figure 1 illustrates,

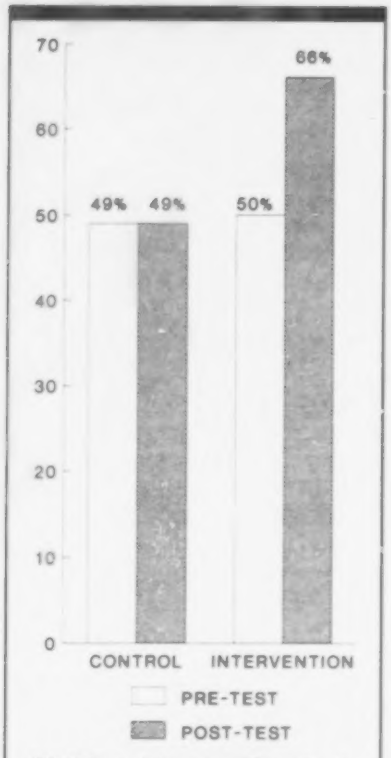

FIGURE 1—The proportion of outdoor workers (control vs intervention groups) using a high level of solar protection during the pre- and posttest periods.

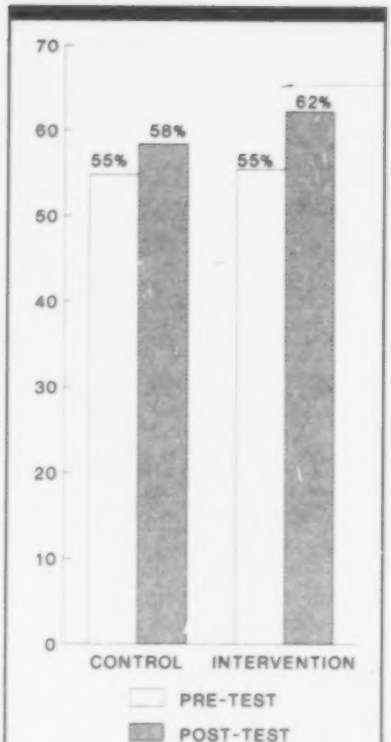

FIGURE 2—The percentage of correct knowledge score (control vs intervention groups) at the pre- and posttest periods.

the proportion of outdoor workers who used high solar protection increased significantly from pre- to posttest in the intervention group ($P < .02$) but did not change in the control group ($P = 1.0$).

Knowledge and Attitudes

A knowledge score was obtained for each group by calculating the average percentage of correct responses from a maximum of 23 points. Between-group knowledge was compared using *t* tests, and within-group knowledge was compared using paired *t* tests. As illustrated in Figure 2, there was no significant difference between the two groups at baseline (intervention = 55%, control = 55%; $P = .774$). While both groups demonstrated a significant improvement in the average percentage of correct knowledge score from pretest to posttest (intervention = $P < .001$; control = $P < .01$), the level at posttest was significantly higher in the intervention group (62% vs 58%, $P < .05$).

An attitude score was calculated by using the factor scores from each of the internally consistent factors, with the most desirable response receiving the maximum score (100%). There were no differences between the two groups either at baseline (intervention = 50%, control = 49%; $P = .567$) or at posttest (intervention = 49%, control = 48%; $P = .449$), and no changes were observed in either group from pretest to posttest.

Discussion

Although outdoor workers are at increased risk of developing skin cancer because of the nature of their occupation,[12–14] no evaluated health promotion activities directly targeting this health problem have been reported in the workplace. The primary aim of this study was to develop and evaluate the effectiveness of a workplace intervention program designed to improve the solar protection behavior and related knowledge and attitudes of a sample of outdoor workers in the Hunter Region.

The results revealed a significant improvement in both the knowledge and the solar protection behavior of the workers who participated in the intervention. This was indicated by an increase of 16% from pre- to posttest in the proportion of workers in the intervention group who used high solar protection, compared with no improvement in overall protection of workers in the control group. Knowledge about skin cancer and solar protection issues was also assessed in this study, and although both groups improved in their average knowledge score, the improvement was significantly greater in the intervention group. Neither group showed any change in their attitudes about skin cancer and solar protection.

The success of this intervention in improving the knowledge and solar protection behavior of the target group may be attributed to a combination of factors. First, the delivery of the intervention through the workplace may have contributed to its success, as previously discussed.[33–38] Given that exposure to the sun is an inherent part of the work environment of outdoor workers, attempts to change the workers' solar protection behavior at the work site are likely to be more successful than less environmentally specific interventions, as supported by the results of this study.

Second, the education session complemented the screening session by providing specific information on the means of modifying the health risk behavior (i.e., solar exposure), thereby addressing personal vulnerability to developing skin cancer. Such information included the opportunities to prevent skin cancer by using both measures that are generally available and measures that are specifically issued in this workplace, such as sunglasses, wide-brimmed hats, wide brims and backflaps for hard hats, sunscreens, long-sleeved shirts, and lightweight overalls. Furthermore, distribution of written information could encourage social support from other members of an individual's household, thereby providing an additional motivation to change.

In conclusion, although the intervention developed and evaluated in this controlled trial was associated with an improvement in both the level of knowledge and the proportion of workers adequately protected, a number of issues need to be addressed in future research. First, the proportion of protected outdoor workers improved 16% after participation in the intervention. While this result may not appear to be substantial, it was achieved by implementing a relatively brief intervention, which consisted of one screening/education session. Since the overall level of protected outdoor workers remains suboptimal in this group (66%), the poten-

tial for achieving greater improvements needs to be examined in future programs. Furthermore, research is required to develop and evaluate interventions that may have a lasting effect on the solar protection of the vulnerable target group.

Second, although the intervention was effective, further programs specifically targeting outdoor workers should be developed and systematically evaluated to assess the relative cost-effectiveness of simple versus more intensive interventions. Ideally, programs incorporating screening should use existing resources within the workplace, such as occupational health and safety officers, whose job description clearly encompasses such health promotion activities. The response of both employees and management in our research suggests that such programs would be well supported.

Finally, while this program focused specifically on individual behavioral change, it is important that the issue of solar protection for outdoor workers be considered on multiple levels. These may include providing educational sessions; adopting and enforcing workplace policies that address protection and screening; providing adequate solar protection items, including lightweight overalls, hats, and sunscreen; providing structural shelters, such as umbrellas or canopies; and restructuring outdoor work to avoid the most harmful period of the day. Each option is associated with some financial as well as administrative costs to the workplace, so the likelihood of a workplace adopting one or a number of these options will depend on available resources and the perceived priority of skin cancer in relation to other workplace health promotion and occupational health and safety issues. However, the long-term benefits in reducing the burden of illness of skin cancer are likely to be substantial. □

Acknowledgments

This research was undertaken by the New South Wales Cancer Council Cancer Education Research Project team, directed by R. Sanson-Fisher.

We gratefully acknowledge the Newcastle Area Dermatologists, including Drs A. Watson, B. Bartlett, R. Gillespe, J. Relic, J. Sippe, and G. Watt; Sisters S. Collins, D. Bradley, and D. Owens of the Newcastle Melanoma Unit; and Tony Tripodi for their involvement in the delivery of the intervention. We also thank the management, the safety officers, and the outdoor workers from Shortland County Council for their support and enthusiastic participation in the study. Finally, we acknowledge the extensive statistical assistance provided by Stephen Halpin and the research assistance provided by Angela Pirona-Barry.

Racial Disparities in Reported Prenatal Care Advice from Health Care Providers

Michael D. Kogan, PhD, Milton Kotelchuck, PhD, MPH, Greg R. Alexander, ScD, MPH, and Wayne E. Johnson, PhD

ABSTRACT

Objectives. The relationship between certain maternal behaviors and adverse pregnancy outcomes has been well documented. One method to alter these behaviors is through the advice of women's health care providers. Advice from providers may be particularly important in minority populations, who have higher rates of infant mortality and prematurity. This study examines racial disparities according to women's self-report of advice received from health care providers during pregnancy in four areas: tobacco use, alcohol consumption, drug use, and breast-feeding.

Methods. Health care providers' advice to 8319 White non-Hispanic and Black women was obtained from the National Maternal and Infant Health Survey.

Results. After controlling for sociodemographic, utilization, and medical factors, Black women were more likely to report not receiving advice from their prenatal care providers about smoking cessation and alcohol use. The difference between Blacks and Whites also approached significance for breast-feeding. No overall difference was noted in advice regarding cessation of drug use, although there was a significant interaction between race and marital status.

Conclusions. These data suggest that Black women may be at greater risk for not receiving information that could reduce their chances of having an adverse pregnancy outcome. (*Am J Public Health.* 1994;84: 82–88)

Introduction

The relationship between maternal health risk behaviors during pregnancy (such as smoking, alcohol consumption, or illegal drug use) and adverse outcomes has been well documented. Maternal smoking has been associated with an increased risk of low birthweight, impaired fetal growth, fetal death, obstetric complications, and infant mortality.[1–4] Heavy alcohol consumption has been linked to a group of anomalies known as fetal alcohol syndrome.[5] Moderate or low alcohol consumption during pregnancy has been related to increased risks for preterm delivery, reduced birthweight, and spontaneous abortions.[6–8] Although it has been suggested that the evidence for linking moderate or low alcohol consumption with adverse outcomes is not conclusive,[9] health education messages continue to advise prudence in or abstinence from alcohol consumption during pregnancy. Illegal drug use, particularly use of cocaine or crack cocaine, has been associated with elevated risks for small-for-gestational-age births, premature births, abruptio placentae, and perinatal deaths.[10,11]

One way to alter these behaviors is through the advice and encouragement of women's health care providers. Most women are seen during the first trimester, when cessation of these behaviors could lower their risk of an adverse reproductive outcome.[12] As such, providers are in an advantageous position to identify pregnant women who are smoking, drinking, or using drugs and to initiate a health education program.[13] Studies have indicated that smokers are more likely to quit after receiving advice from a physician.[14,15]

Advice from providers may be particularly important in minority populations, who have higher rates of low-birthweight infants, premature births, fetal mortality, sudden infant death syndrome, and all-cause infant mortality.[16–18] There have been indications that Black women at high risk of giving birth to a low-birthweight infant may derive more important benefits from prenatal interventions.[19]

Analysis of racial disparities in prenatal care heretofore implicitly assumed that all prenatal care is the same. Yet the content of prenatal care may not be identical for all populations. The equivalency of the content of prenatal care has yet to be demonstrated, especially for all racial groups. Differential prenatal care may lead to differential efficacy and could be a factor in the large differential rates of birth outcomes by race seen in the United States.

Prenatal care interventions may be an important source of ameliorating racial disparities in maternal risk status and ultimately may be important for birth outcomes. A report by the US Public Health Service advocated examining the content of prenatal care.[20] Perceived maternal advice has not yet been extensively examined, especially by race.

The objectives of this study were to (1) examine the percentages of Black and non-Hispanic White women who reported receiving advice from health care providers during pregnancy in four areas: tobacco use, alcohol consumption, drug use, and breast-feeding; and (2) determine whether any observed racial disparities were the result of other contributing factors.

Methods

These objectives were explored with data collected from the 1988 National Maternal and Infant Health Survey conducted by the National Center for Health Statistics. This was a follow-back survey consisting of three groups: 9953 women who had a live birth in 1988, 5332 women who suffered an infant death in 1988, and 3309 women who had a 1988 fetal loss. The survey was designed to be nationally representative and was drawn from the 1988 vital records of 48 states and the District of Columbia (South Dakota and Montana were not included). It included an oversampling of Blacks and low-birthweight infants. Approximately 50% of the respondents were Black, and 30% of the infants in the live birth sample had a low birthweight. Both married and unmarried women were included in the sample.

To adjust for this sampling frame, all live births were sorted into sampling strata formed by information taken from the birth certificate: mother's age and marital status and child's race and birthweight. To ensure an adequate sample size for analysis, different sampling rates were applied to each stratum. The same strata were used as nonresponse adjustment cells. The sample was then adjusted by post-stratification to once again be representative of the United States. A more complete description of the design of the 1988 National Maternal and Infant Health Survey has been published elsewhere.[21]

The National Maternal and Infant Health Survey used a mixed-mode methodology (mail, phone, or personal interview) to collect information from respondents. The response rate for women in the live birth cohort was 74.4%. With respect to birth certificate information, nonresponders were slightly more likely than responders to be Black and unmarried (data not shown).

This investigation included only women in the live birth cohort on the supposition that women with fetal deaths may not have been in care long enough to receive certain types of advice from their providers and that women with infant deaths may recall their prenatal care experiences differently. The study was also limited to White and Black women who reported receiving some prenatal care: 98% of the population. After other racial groups and women who classified themselves as Hispanic were excluded, 8310 women who had a live birth in 1988 were available for analysis. The study population is nationally representative for non-Hispanic White and Black live births only.

The outcome measures used in the present study included the mothers' responses (yes/no) to a series of questions regarding the receipt of any advice or instructions during any of their prenatal visits on (1) trying to breast-feed their baby; (2) reducing or eliminating consumption of alcohol; (3) reducing or eliminating use of tobacco; and (4) not using illegal drugs such as marijuana, cocaine, or crack cocaine.

Maternal race, education, household income, and marital status was determined from the mothers' responses to the questionnaire. Maternal age and the trimester that women began prenatal care was drawn from the birth certificate.

Respondents were asked where they went for most of their prenatal care. They were given a choice of private doctor's or nurse-midwife's office, county or city health department, community health center, health maintenance organization (HMO), work or school clinic, hospital clinic, hospital emergency room, or other site. In the analysis, county or city health department and community health center were combined into a variable called publicly funded sites of care. Work or school clinic and hospital emergency room were included in the "other" category because of small numbers (<1%).

Women were asked how their prenatal care was paid for. The choices were the respondent's or her partner's own income, insurance that the respondent carried or was carried for her, Medicaid, government assistance other than Medicaid (state or local), or other. Women were also asked whether they had received assistance from the Women, Infants, and Children's (WIC) program because women participating in the WIC program are supposed to receive advice on nutrition and health habits.

Information regarding the use of tobacco or alcoholic beverages in the 12 months before the respondents' infants were born was taken from the National Maternal and Infant Health Survey responses. Data on reported drug use were not included because of the known unreliability of such data. The National Maternal and Infant Health Survey did not inquire whether prior infants were breast-fed.

On the supposition that women who had a previous adverse outcome would be more likely to obtain or seek advice, a variable was created that categorized women into three risk groups based on their response to pregnancy history questions: women who did not report a previous pregnancy; women who had a previous pregnancy without an adverse outcome; and women whose previous pregnancy ended in either a stillbirth, miscarriage, abortion, or infant death.

Analysis

Because of the complex sampling method used in the National Maternal and Infant Health Survey, all analyses were weighted to be representative of the US national distribution for non-Hispanic Whites and Blacks.[21]

The data presentation is composed of three sections. First, demographics by race are presented descriptively. Second, the bivariate racial disparities are noted for the four outcome measures, as well as for the covariates. Third, logistic regressions were run to isolate the contributions of race.

Scaled weights were used to perform all analyses. The scaling factor was the reciprocal of the mean weight; the sum of all the scaled weights is the same as the actual number of observations.

The logistic regression analysis controlled for age, marital status, education, income, site of prenatal care, type of payment, maternal health behaviors, trimester that care began, and prior adverse pregnancy outcomes. In addition, interaction terms were examined in the multivariate models. The logistic regression analyses were conducted with the Survey Data Analysis software program.[22] This program was developed specifically for calculating variances in complex sample surveys. Adjusted odds ratios (ORs) and 95% confidence intervals were computed by using the beta coefficients and standard errors obtained from the logistic analyses.

Results

Table 1 shows the characteristics, by race, of the sample of 8310 women from the 1988 National Maternal and Infant Health Survey on all study sociodemographic, health system, health behaviors, and medical history variables, weighted to reflect their real population distributions.

[a]For all analyses, the figures given are the weighted-sample figures.
[b]Women could provide more than one source of payment.

Demographically, Black women giving birth in 1988 were distinct from White women giving birth in 1988. Black women were more frequently single, were less likely to be educated beyond high school, were younger, and had lower incomes. Black women also utilized publicly funded sites of care, the WIC program, and Medicaid programs more frequently than White women. Black women also reported better smoking and drinking health behaviors than White women.

Table 2 shows the bivariate association of race and all study covariates with the four health behavior advice variables. In all four areas, substantial numbers of women did not report receiving health behavior advice. Smoking cessation was the most common advice reported (69.5%), closely followed by cessation of alcohol consumption (68.4%). Receiving breast-feeding advice was reported by only 51% of all women in the United States.

White women reported receiving more prenatal advice on alcohol, smoking, and breast-feeding than did Black women. The disparity was greatest for avoidance of alcohol: only 60% of Blacks reported that they received advice on alcohol avoidance from their prenatal care provider compared with 70% of Whites.

For cessation of alcohol consumption, advice was, in general, substantial for all subgroups, but significantly more frequent for women of higher socioeconomic status (e.g., more often married, more than 12 years of education, and more income). Advice increased with age, through 30–34 years. Not surprisingly, advice on cessation of alcohol consumption was highest for alcohol users (76.1%), but even in those cases, 23.9% of alcohol users did not get advice. Although not presented in Table 2, the racial disparity remained after controlling for drinking status: 76.8% of White women who said they had drunk some alcohol in the 12 months before their delivery reported that they received advice compared with 69.7% of Black drinkers. Disparities across education and income groups seemed slightly stronger than disparities by race.

Advice on smoking cessation appeared to follow a different trend than advice on cessation of alcohol consumption. Demographically, younger women and women with less than 12 years of education received more advice. Income and marital status were less significant. Hospital clinics and other sites of prenatal care were the most likely to give advice; private offices were the least likely. Smoking advice was given to 90.4% of smokers and 59.5% of nonsmokers. Smoking status was, by far, the strongest predictor of smoking advice. Again, though not shown in the data presented, the racial disparity remained after controlling for the behavior status: 91.0% of White women who smoked in the year before delivery reported receiving advice compared with 86.5% of Black women who smoked. Disparities across age, WIC status, and smoking status seemed stronger than disparities by race.

Racial disparities were not noted for advice on cessation of drug use in the bivariate analysis. In general, advice about

cessation of drug use followed a pattern similar to that of smoking advice, with women of poorer socioeconomic status receiving more advice. Advice on cessation of illegal drug use was significantly more frequent for single, less educated, younger, and poorer women. Public clinics gave more advice than private sources of care.

Advice promoting breast-feeding was the advice reported least often. In general, there was some tendency for women of higher socioeconomic status to get more breast-feeding advice. Breast-feeding advice was more frequent in Whites, married women, and women with more than 12 years of education; it was least frequent in the lowest-income women. Site of prenatal care presents a complex picture, with HMOs and publicly funded clinics the most frequent providers of breast-feeding information. WIC participants reported only a 54.7% rate of receiving breast-feeding advice from their health care providers.

Table 3 shows the unadjusted and adjusted ORs (controlling for all variables in the logistic model) for not reporting receipt of advice on each of the four health behaviors, by race. Before adjustment, Black women were significantly more likely to report not receiving advice on cessation of alcohol consumption, smoking cessation, and breast-feeding promotion. After adjustment, a significant racial disparity in advice for alcohol and smoking cessation still remained. Breast-feeding promotion just missed reaching significance and was similarly skewed towards more advice for White women. The unadjusted OR for race in the analysis of drug use cessation was 0.99. When race was analyzed with the covariates, before interaction terms were assessed, the adjusted OR became significant (1.28), indicating that racial disparities were masked in the bivariate analysis. However, there was a significant interaction between race and marital status: Black single women were 1.4 times more likely than White single women not to receive advice on drug use cessation, whereas there were no racial differences among married women.

Table 4 presents the full logistic analysis for each of the outcome variables. For advice on cessation of alcohol consumption, only six variables were significant: drinkers were more likely to be given advice; and older women (>35 years), women with less than 12 years of education, Black women, WIC nonparticipants, and women who began prenatal care after

TABLE 3—Unadjusted and Adjusted Odds Ratios Comparing Blacks with Whites on Prenatal Care Advice in the 1988 National Maternal and Infant Health Survey

Outcome	Unadjusted OR (95% CI)	Adjusted OR (95% CI)
Did not receive drinking cessation advice	1.57 (1.41, 1.74)	1.29 (1.10, 1.51)
Did not receive smoking cessation advice	1.35 (1.21, 1.50)	1.20 (1.01, 1.39)
Did not receive advice on breast-feeding	1.22 (1.11, 1.35)	1.15 (0.99, 1.32)
Did not receive advice on illegal drug use	0.99 (0.89, 1.09)	1.28 (1.10, 1.48)[a] 1.01 (0.65, 1.57)[b]

Note. OR = odds ratio; CI = confidence interval.
[a]Model without interaction.
[b]Model with significant interaction.

the first trimester were all less likely to be given advice.

For advice on smoking cessation, there were seven significant factors. Smokers were substantially more likely than nonsmokers to receive advice. Older and separated women received less smoking cessation advice. Although the bivariate analysis indicated that income was not significant, the multivariate analysis showed that lower-income women with incomes of less than $6 000, $6 000–$11 999, and $12 000–$17 999 received less advice than upper-income women. WIC nonparticipants also reported less advice.

For breast-feeding promotion, there were six significant factors, and each was stronger than race. Single women, women with less than 12 years of education, women with the lowest income levels, and WIC nonparticipants received less advice promoting breast-feeding. Women who received most of their prenatal care at publicly funded sites or HMOs or who had no private insurance were more likely to report receiving advice than women who received care at private physicians' offices.

Three factors predicted not receiving drug cessation advice. Race, in the presence of interaction, was not significant. Older women (ages 30–34 and 35+ years) and WIC nonparticipants received less advice; women who used either public prenatal care sites or hospital clinics received more advice than those who received care at private offices. Once again, WIC nonparticipants received less advice.

Interaction terms (with race) were examined for each of the four health behavior outcome measures. They were not significant or informative for smoking, alcohol, or breast-feeding advice. A significant interaction term (race by marital status) was noted for illegal drug use (OR = 1.43).

Discussion

Advice about prenatal health behavior is not a uniform feature of all prenatal care. Regardless of race, one third or more of the women surveyed reported receiving no prenatal advice on alcohol, tobacco, or drug use, and approximately 50% received no prenatal information on breast-feeding. The observation that women who smoked or drank were more likely to report receiving prenatal advice on tobacco or alcohol use is a positive indication that services were being targeted to at-risk groups. Notwithstanding, given the emphasis placed on the importance of providing all women with prenatal advice on substance use and breast-feeding, these findings indicate that much improvement is still needed in the content of prenatal care being provided to women in the United States.

The content of prenatal care is not uniform across racial groups. Compared with White women, Black women receiving prenatal care advice were significantly less likely to report receiving advice on drinking and smoking cessation, and the disparity in breast-feeding advice approached significance. This is the other critical finding of the study.

The current analyses suggest that although race is an important factor in the content of prenatal care, other programmatic and sociodemographic factors are equally, if not more, important. First, advice about two of the behaviors, smoking and drug use, was skewed towards poorer women, whereas advice about alcohol use and breast-feeding was skewed towards wealthier women. Health care providers may be giving advice based on their stereotypes of who is involved in what type of behaviors and not on a principal of equity. Second, the site of prenatal care was important. Advice on illegal drug use was more common for patients of publicly funded sites and hospital clinics than for private-office patients. Patients of HMOs and publicly funded sites were also found to have a lower risk of not receiving breast-feeding advice compared with private-office patients. Third, participation in the WIC program, which mandates prenatal care advice on these behaviors as part of its basic package of services,[23,24] had a protective effect in each multivariate analysis, with WIC nonparticipants reporting less prenatal advice. Fourth, older women (>35 years of age) were more likely to report not receiving advice on alcohol, tobacco, and drug use. This finding may reflect a perception on the part of the providers that these women were in less need of this advice because of earlier pregnancies, particularly in the case of illegal drug and alcohol use. Alternatively, providers may have perceived that these messages would be less effective in terms of changing established behaviors (e.g., tobacco use) and consequently may have stressed them to a lesser degree.

Although interactions were explored for each of the outcome measures, a significant interaction between marital status and race was only identified in the analysis of advice on illegal drug use. This finding suggests that White single women were targeted for advice on illegal drug use more often that Black single women or tended to report receiving such advice in greater proportions. These data are insufficient to propose an explanation for these findings. Illegal drug use is a sensitive area of discussion, and further investigation of these findings may need to explore to what extent differences in ethnic and cultural characteristics of providers and patients may inhibit the provision of advice in this area.

This study is limited in that it is based on the self-reports of the women surveyed. It is unclear whether women may be more likely to overestimate or underestimate the actual receipt of prenatal advice or whether error rates vary by type of advice, site of prenatal care, ethnicity of the mother, birth outcome, or other factors. Some studies have found that maternal recall is relatively accurate for birth outcomes,[25,26] whereas maternal recall of exposures during pregnancy has been mixed.[27,28] Moreover, patients and providers may have different recall on the content of a visit.[29] Nonetheless, it is women's perception, not the providers' report of their practice, that is ultimately most likely to be linked to health behavior changes.

Over the last two decades, considerable emphasis has been placed on the importance of adequate prenatal care for minority populations, who have been identified as having a greater risk of poor pregnancy outcome. To the extent that health care educational messages and campaigns have been effective, one might hypothesize that minority women who do receive prenatal care would be more likely than White women to be given information on these topics. These data indicate that this is not the case and suggest the need for continued and expanded medical education programs to increase provider awareness of the importance of these issues as part of prenatal care services to all women, particularly women at higher risk of poor pregnancy outcome.

The findings that there are variations in the content of prenatal care by ethnicity of the mother, site of care, and age, among other factors, also have implications for the interpretation of investigations focusing on the impact of the adequacy of prenatal care, as measured by the month of initiation of prenatal care and by the number of prenatal care visits. Indices of prenatal care utilization have been used to investigate ethnic differences in pregnancy outcome.[30,31] Although ethnic variations in prenatal care utilization have been repeatedly uncovered, the magnitude of these variations was insufficient to explain prevailing ethnic disparities in pregnancy outcome measures. The present findings, indicating that the content of prenatal care is not consistent for all ethnic groups, must now be considered as another potential explanation.

However, it should be stressed that although these data suggest that Black women receive less prenatal care advice on alcohol and tobacco use, it would be imprudent to overspeculate on whether these ethnic differences in the content of prenatal care advice are likely to appreciably explain the observed ethnic disparities in pregnancy outcome—given the lower likelihood of Black women's smoking and drinking before delivery. However, the content of prenatal care and the linkage of content and maternal needs in our understanding of the causes of racial disparities in birth outcomes must now be considered.

Conclusion

The present study suggests that large numbers of women of all races do not receive sufficient health behavior modification information as part of the content of their prenatal care. In particular, Black

TABLE 4—The Odds of Not Receiving Advice on Prenatal Care Behaviors during Pregnancy

Infant Feeding Policies in Maternity Wards and Their Effect on Breast-Feeding Success: An Analytical Overview

ABSTRACT

Objectives. The purpose of this review is to examine the plausibility of a causal relationship between maternity ward practices and lactation success.

Methods. Studies were located with MEDLINE, from our personal files, and by contacting researchers working in this field. Of the 65 studies originally reviewed, 18 met our inclusion criteria (i.e., hospital-based intervention, experimental design with randomization procedures, or quasi-experimental design with adequate documentation).

Results. Meta-analysis indicated that commercial discharge packs had an adverse effect on lactation performance. The impact of early mother-infant contact on lactation success was unclear. Rooming-in and breast-feeding guidance in a rooming-in context had a beneficial impact on breast-feeding among primiparae. Breast-feeding on demand was positively associated with lactation success. In-hospital formula supplementation of 48 mL per day was not associated with poor breast-feeding performance.

Conclusions. Hospital-based breast-feeding interventions can have a beneficial effect on lactation success, particularly among primiparous women. (*Am J Public Health.* 1994;84:89–97)

Introduction

The recent interest in maternity ward practices demonstrated by international health agencies[1] is justified. Rooming-in can have a beneficial impact on the health of the newborn,[2–4] and, as this review will show, there are strong reasons to believe that beneficial infant feeding policies in the maternity ward can contribute to lactation success. In 1989, the World Health Organization (WHO), in conjunction with the United Nations Children's Fund (UNICEF),[1] made several recommendations to promote breast-feeding in institutions that provide maternity services. These recommendations included rooming-in throughout the hospital stay, breast-feeding on demand, early initiation of breast-feeding, breast-feeding guidance by health personnel, and avoidance of supplementary fluids. Given the high number of births attended in clinics or hospitals worldwide,[4,5] an in-depth assessment of the impact of such policies is worthwhile.

In 1980, Winikoff and Baer[6] concluded that maternity ward policies similar to those advocated by WHO and UNICEF could have a positive impact on breast-feeding. However, they did not fully address the methodological limitations of the studies included in their review. Although Margen et al.[7] recognized that the majority of such studies did not account for confounders, they too concluded that lactation performance can be improved by encouraging mother-infant contact, providing breast-feeding information, and restricting bottle-feeding. Their conclusion may have been premature, however, since the only published study[8,9] on which they based their conclusion regarding long-term effects had serious methodological limitations.[10]

Bernard-Bonnin et al.[11,12] integrated the results of nine studies and used meta-analysis to test the effects of four different maternity ward policies on breast-feeding success. The authors concluded that lactation success was improved by both early mother-infant contact and breast-feeding support by health personnel with phone follow-up, but that in-hospital formula supplementation and breast-feeding support without phone follow-up had no significant impact. Their review did not consider policies such as discharge packs, rooming-in, and breast-feeding on demand, and it did not include any studies in developing countries.

Considering the limitations of these previous reviews, it is worthwhile to reexamine this issue. The intent of our review is to examine the plausibility of a causal relationship between maternity ward practices and lactation success, using the procedures of meta-analysis whenever possible.

Methods

This review is restricted to articles on the relationship between maternity ward practices and lactation success published in English or Spanish between 1951

Rafael Pérez-Escamilla, Bo Lönnerdal, and Kathryn G. Dewey are with the Department of Nutrition and the Program in International Nutrition, Dr Lönnerdal is also with the Department of Internal Medicine, and Ernesto Pollitt is with the Department of Pediatrics and the Program in International Nutrition, University of California at Davis.

and 1991. Studies were located with MEDLINE, from our personal files, and by contacting researchers working in this field.

The initial screening criterion was that the studies should involve randomized trials or quasi-experimental designs. Of the 65 studies that were identified,[8,9,13–76] 35 met this criterion. Next, those studies with questionable internal validity (i.e., those that contained between-group socioeconomic differences [two studies],[24] self-selection of participants,[16,22,35] assignment to group based on physician's wishes,[20] and exceedingly high and unevenly distributed attrition rates[63] were eliminated. Also eliminated were those studies that did not provide enough information for their internal validity to be determined (i.e., they had unreported attrition,[40,64] poorly documented methodology,[21,37] or were unpublished brief communications[39,71]). Studies based on planned (vs practiced) breast-feeding behavior[46] or confounded by birth method (vaginal vs c-section)[65] or postdischarge breast-feeding interventions[66–68] were also excluded. In total, 12 out of 28 randomized studies and 5 out of 7 quasi-experimental studies were subsequently excluded.

Whenever possible, meta-analysis[77] was used to pool and interpret results across studies.

Results

The studies were grouped according to several of the policies in the WHO/UNICEF recommendations. The categories are commercial discharge packs, rooming-in and breast-feeding guidance, early maternal-infant contact, breast-feeding on demand, and in-hospital formula supplementation.

Commercial Discharge Packs

Following the 1981 WHO code for the marketing of breast milk substitutes,[78] five clinical trials were conducted in developed countries[27–31] and one in a developing nation[32] to test the effects of commercial discharge packs on lactation success (Table 1). Sample size ranged from 87 to 406 subjects. All the studies were conducted in urban areas, but there were differences between studies in the ethnic and socioeconomic characteristics of subjects.

In all studies, women were randomly assigned either to a group that received commercial discharge packs or to a control group. In half of the studies,[29–31] women in the control group received a research discharge pack (i.e., a pack with breast-feeding promotion materials); in the remaining three studies,[27,28,32] there was no intervention for controls. The con-

tent of the discharge packs is described in Table 1. We used meta-analysis[77] to examine the effect of commercial discharge packs on (1) any breast-feeding at 1 month, (2) full breast-feeding (i.e., breast milk as the only source of milk) at 1 month, and (3) any breast-feeding at 4 months. The results (Table 2, Figure 1) indicate that the distribution of commercial discharge packs had a detrimental effect ($P < .05$) on full breast-feeding at 1 month and on any breast-feeding at 4 months, and a marginal effect on any breast-feeding at 1 month.

The study conducted by Guthrie et al.[32] was the only one carried out in a developing country. Initially, the authors collected data for 8 months postpartum from poor women delivering in two public hospitals (hospitals A [n = 134] and B [n = 79]) in the Philippines. In each hospital, women were randomly assigned to a group receiving a free can of formula at hospital discharge or to a control group not given formula. In hospital A there was a trend toward lower breast-feeding rates among formula recipients, but in hospital B formula recipients tended to be more likely to breast-feed. However, the results from hospital B do not warrant conclusive inferences since the experimental group was very small (only 17 subjects at the end of the study). The authors "replicated" their original study in a third hospital and concluded that formula recipients were not less likely to breast-feed than controls. However, these women were followed for only 2 months rather than for 8 months.

We reanalyzed the data from hospital A using survival analysis[79] (instead of the chi-square analyses at different time points conducted in the original paper) and found that women who received the free can of formula were less likely to breast-feed ($P < .05$, one tail) during the first 8 months after delivery (Figure 2). This suggests that commercial discharge packs can have a negative impact on the lactation success of women in developing countries.

Another study that deserves further discussion is that of Bergevin et al.,[27] who documented that the negative impact of commercial discharge packs is more pronounced among vulnerable subgroups (e.g., primiparae, mothers with less education, and mothers who were ill after delivery). Evans et al.[28] could not replicate these findings; however, the sample sizes of the subgroups in their study were very small.

To summarize, commercial discharge packs are linked to poor lactation

TABLE 2—Homogeneity Test and Fisher's Combined Test of Studies Comparing Lactation Performance among Recipients (CDP) and Nonrecipients (NCDP) of Commercial Discharge Packs

Study	CDP Breast-Feeding % (n)	NCDP Breast-Feeding % (n)	One-Tail P	Y[a]	Homogeneity Test[b]	"χ^{2}"	Fisher's Combined Test[d]

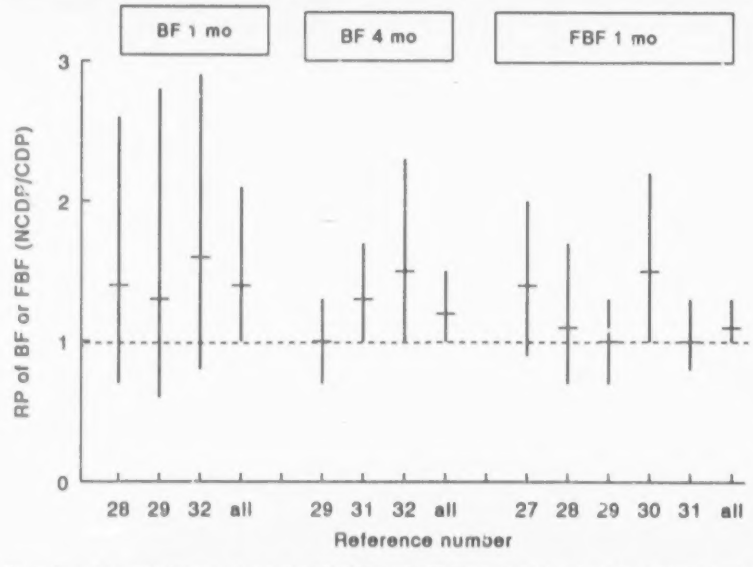
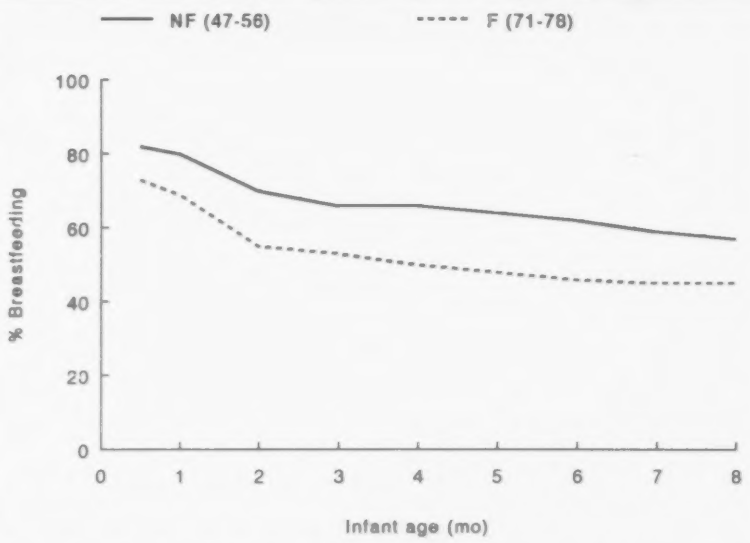
Feinstein et al.[29]	58 (76)	56 (90)	.82[f]	1.74		1.0	
Frank et al.[31]	55 (167)	65 (156)	.04	0.12		6.4	

[a] $Y = w(d - \bar{d})^2$, where $d = 2^*\text{ln}(1 - r^2)^{1/2}$, $r = (\chi^2/N)^{1/2}$, $w = 2^*N/(8 + d^2)$, $\bar{d} = \Sigma wd/\Sigma w$. N = study sample size, χ^2 = chi-square value.[77]
[b] Based on formula $\chi^2 = \Sigma w^* (d - \bar{d})^2$, with $K - 1$ degrees of freedom (where K = number of independent studies).[77]
[c] "χ^{2}" = $-2^* \log_e$ (one-tailed P).[77]
[d] $\chi^2 = \Sigma$"χ^{2}" with $2n$ degrees of freedom (where n = number of independent studies).[77]
[e] Breast-feeding 6 to 7 weeks after delivery.
[f] CDP group had higher breast-feeding rates than NCDP group. Therefore, $P_{1\text{tail}} = 1 - P_{2\text{tail}}/2$.[77]



Note. The horizontal lines indicate the RP of BF or FBF. The vertical lines depict the upper and lower bounds of the 95% confidence interval (CI) of the RP of BF or FBF (based on Mantel-Haenszel statistics). The RP of BF at 1 month with all studies combined (all) is 1.4 (95% CI:1.0, 2.1). The RP of BF at 4 months with all studies combined (all) is 1.2 (95% CI:1.0, 1.5). The RP of FBF at 1 month with all studies combined (all) is 1.1 (95% CI:1.0, 1.3).

FIGURE 1—Relative probability (RP) of postpartum breast-feeding (BF) or full breast-feeding (FBF) associated with receipt of commercial discharge packs (CDP) vs nonreceipt (NCDP), by study.



Note. F (n = 71–78) = can of powdered formula at discharge; NF (n = 47–56) = no formula provided at discharge. Based on data from Guthrie et al.[49]

FIGURE 2—Effect of formula samples at discharge on lactation success of Filipino women.

success, particularly among vulnerable subgroups such as primiparae and poor women in developing countries.

Rooming-In and Breast-Feeding Guidance

Only two studies that examined rooming-in and breast-feeding guidance[33,34] met our inclusion criteria. Since one of these two studies evaluated both rooming-in *and* breast-feeding guidance, these policies are discussed jointly in this section.

Lactation success of low-income primiparous women was studied in Managua, Nicaragua.[34] During the first 3 months of recruitment, mothers were randomly assigned to one of two groups: (1) complete maternal/infant separation throughout hospitalization with little or no breast-feeding promotion (n = 123), or (2) 45 minutes of maternal/infant contact immediately after birth followed by complete separation until discharge (n = 136). Women in the latter group received breast-feeding promotional messages. During the fourth and last month of recruitment, all eligible subjects were assigned to total rooming-in and to receive breast-feeding promotional messages (n = 116). Mothers and interviewers were blind to the study's hypotheses.

Groups were similar in several socioeconomic and demographic characteristics but differed in birthweight and obstetric procedures. None of the variables that differed was associated with lactation performance. At 1 week, the total rooming-in plus breast-feeding promotion group had a higher incidence ($P < .05$) of exclusive (63% vs 32%) and of any breast-feeding (93% vs 82%) when compared with the complete separation group. At 4 months, the differences between groups were not significant, but when the complete separation and the early contact plus breast-feeding promotion groups were combined, their breast-feeding rate at 4 months was lower ($P < .05$) than that of the total rooming-in plus breast-feeding promotion group (39% vs 50%). Thus, rooming-in accompanied by breast-feeding promotional messages had a positive impact on short- and longer-term breast-feeding success. However, this conclusion is tentative since, as recognized by the authors, the groups were not all randomly assigned, and between-group differences at baseline were identified. It was not possible to examine the effect of rooming-in by itself since breast-feeding messages were also provided to the total rooming-in group.

Pérez-Escamilla et al. conducted a study[33] among 165 low-income urban Mexican women who planned to partially or exclusively breast-feed. Women delivered in two different public hospitals. In one, infants were kept in a nursery (n = 58) and their diets were routinely supplemented with formula. In the other, rooming-in was the policy and formula supplementation was not allowed; in this hospital, women were randomly assigned to a group that received individual breast-feeding guidance during the hospital stay (n = 53) or to a control group in which normal routines were followed (n = 54). The groups were very similar in demographic and socioeconomic characteristics, prenatal care, breast-feeding motivation, previous breast-feeding exposure, maternal and infant anthropometry, and infant gender. None of the women mentioned infant feeding policies as a reason for choosing to deliver in a particular hospital.

Among primiparae, rooming-in (vs nursery) was associated with higher rates of full breast-feeding in the shorter but not in the longer term, whereas rooming-in plus breast-feeding guidance was associated with higher full breast-feeding rates throughout the 4-month study. These results suggest that rooming-in might not have a long-term effect unless it is accompanied by breast-feeding guidance. Rooming-in did not have any impact on lactation performance of multiparae. The quasi-experimental nature of this part of the study precludes causal inferences. However, the similarities in characteristics of the groups at baseline lend strength to the conclusions.

Among primiparae in the rooming-in hospital, the rate of decline in breast-feeding was significantly faster among those women who were only rooming-in than among those women who were rooming-in and receiving breast-feeding guidance. No significant differences between groups were found among multiparae. Because this part of the study included random assignment, it was concluded that the better lactation performance observed among primiparae in the rooming-in plus breast-feeding guidance group was indeed a result of the breast-feeding guidance intervention.

To summarize, the two studies that met our inclusion criteria suggest that both rooming-in and breast-feeding guidance in a rooming-in context can have a positive impact on lactation success among primiparae.

Early Maternal-Infant Contact

The handling of the newborn in most maternity wards involves routine procedures that cause maternal/infant separation soon after delivery. This separation may last a few (2 to 4) hours in wards with rooming-in or might continue until hospital discharge in wards with separate nurseries.[4,7]

TABLE 3—Randomized Studies on the Effect of Early Contact on Lactation Performance

Authors	Reference No.	n	Intervention	Country	Population Characteristics
Sosa et al.[a]	24	40	Initiated with nude infant on delivery table Duration: 45 min Dyad separated after contact and reunited 12–24 h postpartum	Guatemala	Urban poor primiparae Vaginal delivery Healthy term infant Birthweight: 2.04–3.85 kg
Ali and Lowry[b]	25	72	Skin-to-skin contact initiated shortly after delivery Contact duration: 45 min Dyad reunited 9 h after delivery	Jamaica	Urban poor primiparae and multiparae Vaginal delivery Full-term newborn Mean birthweight: 3.1 kg

[b]Interviewer(s) were blind to group assignment; subjects were unaware of study design.
[c]Mailed questionnaire; not known if subjects were unaware of study design.

Based on our initial screening criteria (i.e., randomized trials or quasi-experimental designs), we reviewed 14 studies[13,17,22,24(3 studies),25,34,35–40] on the effect of early contact on lactation success. Six of these studies were subsequently excluded[24(2 studies),35,37,39,40]; three of these[35,37,39] reported a positive impact of early contact on postpartum breast-feeding success whereas three[24,40] did not. Of the eight controlled trials that will be discussed, one[13] did not include a follow-up and therefore was not included in the meta-analysis. All except one of the trials in the meta-analysis[25] (Table 3) included only primiparae; three[24,25,34] were conducted in developing countries. Sample sizes ranged from 30 to 259. In all studies, women were randomly assigned to an "early contact" or a control group. In general, early contact meant that mother and newborn were allowed to have skin-to-skin contact beginning up to 39 minutes after delivery and lasting 10 to 45 minutes. In three studies,[22,34,38] mothers were encouraged to breast-feed during the period of early contact; there is no information on this issue in the remainder of the studies. It was reported that partners of the women were allowed to be present during early contact in three studies.[22,36,38] In four studies,[24,25,34,38] the infants were separated from their mothers after early contact and reunited later (within 9 to 24 hours, or at discharge). In the remaining studies, it is not clear if the newborns remained with their mothers after early contact.

Meta-analysis indicated that early contact had a beneficial effect ($P < .05$) on the likelihood of breast-feeding at 2 to 3 months among primiparae (Table 4, Figure 3). However, these results should be interpreted with caution for two reasons. First, the effect size across studies was heterogeneous. This was mainly due to the study conducted in Nicaragua,[34] which found very similar breast-feeding rates among early and delayed contact groups. Second, it may not be possible to attribute improved breast-feeding rates directly to early contact since several studies also included breast-feeding guidance by health personnel or the presence of the father during early contact.

Woolridge et al.[13] conducted a clinical trial in Thailand to study the effect of early contact on the onset of milk production. Twelve dyads (i.e., mother-infant pairs) were randomly assigned to the comparison group, which included infants placed in a separate nursery and given water but not formula. About 24 hours after delivery, the newborns were returned to their mothers, who bedded-in throughout the hospital stay. Thirteen dyads were assigned to the early contact group, in which the newborns were brought to their mothers, fasted 2 to 4 hours after delivery, and remained with their mothers thereafter. The onset of milk production was assessed by test weighing a single feed each day on days 2 to 5 postpartum.

TABLE 4—Homogeneity Test and Fisher's Combined Test of Studies Comparing Lactation Performance at 2–3 Months among Regular Contact and Early Contact Groups

Study	Regular Contact % Breast-feeding (n)	Early Contact % Breast-feeding (n)	One-Tail *P*	Y[a]	Homogeneity Test[b]	$-\chi^{2}$[c]	Fisher's Combined Test[d]

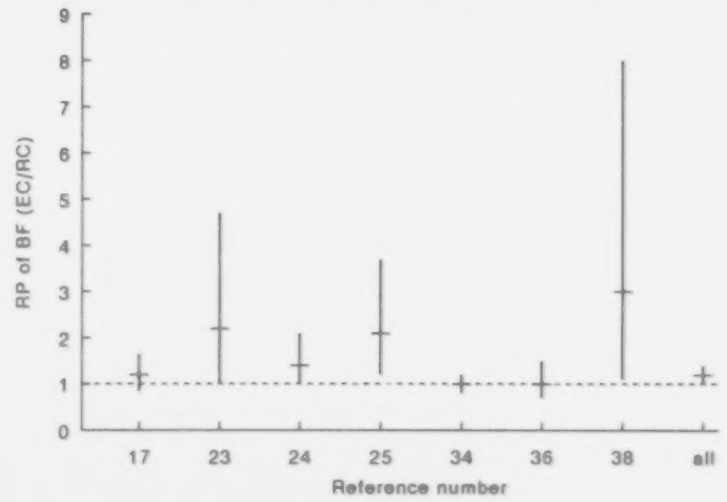
[a] $Y = w(d - \bar{d})^2$, where $d = 2^n r/(1 - r^2)^{1/2}$, $r = (\chi^2/N)^{1/2}$, $w = 2^n N(B + d^2)$, $\bar{d} = \Sigma wd/\Sigma w$. N = study sample size, χ^2 = chi-square value.[77]
[b] Based on formula $\chi^2 = \Sigma w^n (d - \bar{d})^2$ with $K - 1$ degrees of freedom (where K = number of independent studies).[77]
[c] $-\chi^{2n} = -2\Sigma \log_e$ (1-tailed P).[77]
[d] $\chi^2 = \Sigma\ -\chi^{2n}$ with $2n$ degrees of freedom (where n = number of independent studies).[77]
[e] Breast-feeding at 4 months.
[f] If reference 34 is excluded from meta-analysis, the effect size of remaining studies is homogeneous ($\chi^2_{df=5} = 6.3$ [$P > .05$]).
[g] Full breast-feeding at 2–3 months.



Note. The horizontal lines indicate the RP of BF. The vertical lines depict the upper and lower bounds of the 95% confidence interval (CI) of the RP of BF (based on Mantel-Haenszel statistics). The RP of BF at 2–3 months with all studies combined (all) is 1.2 (95% CI 1.0, 1.4).

FIGURE 3—Relative probability (RP) of breast-feeding (BF) 2–3 months after delivery associated with early contact (EC) vs regular contact (RC), by study.

The groups were similar in birthweight, parity, infant gender, and time of day at which milk intake was estimated on day 5. There was a difference of 21.5 hours in mean age at first contact and of 22.4 hours in mean age at first breast-feeding episode between the early contact and comparison groups, but there were no significant differences in milk production. However, the authors caution that the external validity of their findings may be limited since the study was conducted in a traditional society where the infants not only roomed-in but also bedded-in with their mothers. They also acknowledge that the effect of contact within the first 1 to 2 hours after delivery on the initiation of lactation was not studied.

Results presented in this section suggest that early maternal-infant contact might have a beneficial effect on lactation performance. However, to confirm this finding, additional studies with more rigorous methodology are needed.

Breast-Feeding on Demand

Three experimental studies[17,18,42] examined the impact of breast-feeding on demand.

Salariya et al.[17] studied the effect of both the timing of initiation of breast-feeding and the frequency of nursing during the hospital stay on the lactation success of 111 primiparous women. Women were stratified according to age and social class and were randomly assigned to follow one of four sets of feeding instructions: (1) 2E = early initiation (within 10 minutes after delivery), followed by nursing every 2 hours (n = 29); (2) 4E = early initiation, then nursing every 4 hours (n = 27); (3) 2L = later initiation (4 to 6 hours after delivery), followed by nursing every 2 hours (n = 27); and (4) 4L = later initiation, then nursing every 4 hours (n = 28). A questionnaire was mailed at 6 weeks, 12 weeks, and 18 months after delivery to assess infant feeding practices.

At 48 hours, the mothers who breast-fed every 2 hours (2E and 2L) were more likely to report onset of milk production than those who fed every 4 hours (4E and 4L) (54% vs 18%). Compared with infants fed every 4 hours, significantly fewer newborns fed every 2 hours required supplementary formula feeding (28% vs 9%). Median breast-feeding duration was longest in group 2E (182 days), followed by 4E (140 days), 2L (112 days), and 4L (77 days). It was concluded that both early initiation and increased frequency of breast-feeding improved lactation success. However, these results should be interpreted with caution because compliance by the mothers and blindness of interviewers to group assignment were not documented, the methodology used to evaluate the onset of milk production was not described, and no statistical tests comparing the median breast-feeding durations were reported.

De Carvalho et al.[18] conducted a study in the United States to investigate the effects of frequent and unrestricted breast-feeding on infants' milk intake and growth during the first month. Mothers delivering in July and August were told to feed their infants following the 3- to 4-hour hospital schedule (control group). Mothers delivering during September and October were encouraged to nurse on demand (experimental group). Breast-

feeding began within 6 hours after delivery. During the first 14 days, mothers recorded each breast-feeding. Milk intake was measured by test weighing on days 15 and 35. Initially, there were 47 control subjects and 28 experimental subjects. The dropout rates at 1 month were 66% and 57%, respectively.

Maternal age and parity were similar between groups, but mean birthweight was 478 g higher in the experimental group. Nursing frequency during the first 14 days was significantly higher in the experimental than in the control group (9.9 ± 1.9 vs 7.3 ± 1.4), but total nursing duration was similar (135 vs 138 min/24 h). Infants in the experimental group consumed significantly more milk on day 15 (725 vs 502 mL/24 h) and had gained significantly more weight since birth (561 vs 347 g) than those in the control group. At 35 days, nursing frequency was still significantly higher in the experimental group (9.8 ± 2.4 vs 6.8 ± 1.2), but the difference in total nursing duration was again not significant (177 vs 152 min/24 h). Infant milk intake on day 35 was marginally higher ($P = .08$) in the experimental group (841 vs 681 mL/24 h).

The authors concluded that frequent and unrestricted breast-feeding increases early milk production and infant weight gain. However, the between-group difference in birthweight is a potentially important confounding variable. Previous work by the same authors[41] indicated that birthweight was positively associated with nursing frequency and duration at 2 weeks, and others have shown that birthweight is correlated with breast milk intake.[40] In addition, the dropout rates were high and unevenly distributed across groups, and the potential self-selection bias caused by this was not assessed.

Illingworth et al.[42] conducted a study to determine the effect of in-hospital nursing on demand on the lactation performance of 241 mothers in Great Britain. All infants roomed with their mothers and in the first 2 days were breast-fed every 6 hours. On the third day, infants on one floor were fed every 4 hours (n = 106) while those on another floor were fed on demand (n = 131).

There were no significant between-group differences in parity or length of hospital stay. On the ninth day, significantly more newborns in the on-demand group had regained their birthweight as compared with the group fed on schedule (49% vs 36%). At 1 month, significantly more infants in the on-demand group were fully breast-fed (80% vs 64%). Moreover, significantly fewer mothers in that group had experienced sore nipples (13% vs 27%) or breast engorgement (17% vs 34%). Despite the intervention, there were no significant between-group differences in nursing frequency during the first week. However, it must be noted that nursing frequency for the group fed on schedule was assumed to be the six feedings that were scheduled.

In this study it is not known if the nurses, follow-up interviewers, and mothers were blind to the main goals of the study, and the assumption about group equivalence was based on two parameters only.

Although the three studies reviewed above all indicated a significant relationship between advice to breast-feed on demand and lactation success, serious methodological problems preclude any definitive conclusions.

In-Hospital Formula Supplementation

The practice of supplementing infants' diets with formula in the maternity ward is still pervasive. Only one study on this issue met our inclusion criteria.

Gray-Donald et al.[43] conducted a clinical trial in Montreal, Canada, to study the effect of in-hospital formula supplementation on the duration of breast-feeding. Subjects were assigned, based on bedspace availability, to one of two similar but separate maternity wards. In the formula supplementation group, the usual hospital routine was followed: all infants were given formula at 2 AM unless the mothers requested otherwise. Glucose water feedings were not restricted. The usual postpartum stay was 4 days. In the restricted formula nursery, mothers were routinely awakened at 2 AM to breast-feed; their infants were not supplemented with formula unless the mother requested it. Women were interviewed at 9 weeks postpartum by an interviewer blind to group assignment. Breast-feeding was defined as no more than one bottle-feeding per day.

The restricted formula (n = 388) and formula supplementation (n = 393) groups were very similar in birthweight and in socioeconomic and demographic characteristics. The percentage of infants unsupplemented in the hospital was significantly lower in the restricted formula than in the formula supplementation group (15% vs 63%), but the percentage receiving glucose water was similar. The percentage of mothers breast-feeding was very similar between groups at both 4 (71% vs 68%) and 9 weeks (55% vs 54%). No significant differences were observed even after reanalyzing the data using various breast-feeding definitions and within vulnerable subgroups.

The authors caution against generalizing from their findings. In-hospital supplementation was only 48 mL of formula per day. This contrasts sharply with the much higher amount of supplementation that has been reported in maternity wards in developing countries.[7]

Conclusions

This review presents strong evidence that several of the infant feeding policies recommended by WHO and UNICEF (i.e., discontinuation of commercial discharge packs, rooming-in, and breast-feeding guidance) can have a positive impact on lactation success. On the other hand, it also shows that the impact of other maternity ward policies (i.e., breast-feeding on demand) could not be properly evaluated because of serious methodological problems in the studies. Although our analysis suggests that early mother-infant contact might be related to lactation success, the meta-analysis was not easily interpretable due to study heterogeneity. Further clinical trials that control for confounders, such as husband's presence and breast-feeding guidance by health personnel, are required to confirm this relationship. The lack of effect of in-hospital formula supplementation on lactation performance of Canadian women[43] does not preclude the possibility that this practice has a negative impact on breast-feeding in settings where much higher levels of formula supplementation are common.[7] The potential differential impact of breast-feeding promotion efforts within vulnerable subgroups (e.g., low-income women and primiparae) deserves further consideration.

This review was restricted to infant feeding policies in maternity wards; we know almost nothing about the potential synergistic effect that these policies might have when combined with prenatal and postnatal breast-feeding interventions. It is important to fill in these gaps in knowledge in order to tailor cost-effective interventions whose aim is to increase the chances of lactation success and ultimately improve infant health. □

Acknowledgment

We are very grateful to Janet M. Peerson for her statistical advice and guidance with the meta-analyses.

Correlates of High-Density Lipoprotein Cholesterol in Black and White Women

Gregory W. Heath, DSc, MPH, Caroline A. Macera, PhD, Janet B. Croft, PhD, Marcia L. Mace, MSPH, Thomas Gillette, MPH, and Frances C. Wheeler, PhD

ABSTRACT

The relationships of high-density lipoprotein (HDL) cholesterol with body composition, leisure-time physical activity, cigarette smoking, and education were examined in a community-based sample of 480 Black and 1337 White women. Univariate and multivariate analyses indicated inverse associations of HDL with body mass index and waist-to-hip ratio in both groups, and with cigarette smoking and low educational attainment among White women only. Since correlates of HDL cholesterol differ for Black and White women, further investigation of the differences in these correlates is warranted. (*Am J Public Health.* 1994;84:98–101)

Introduction

Low levels of high-density lipoprotein (HDL) cholesterol are independent predictors of coronary heart disease,[1] and high levels of HDL appear to be effective in preventing coronary heart disease in both Whites[2] and Blacks.[3,4] Although HDL levels are higher in women than in men,[5,6] very little information is available about the determinants or correlates of HDL in women, and especially Black women. Thus, associations of HDL with age, body mass index, waist-to-hip ratio, leisure-time physical activity, cigarette smoking, and educational attainment were examined in 1337 White women and 480 Black women.

Methods

Residents of two South Carolina towns were selected in 1987 by using random-digit dialing for households with telephones and simple random selection from city directories for households without telephones. Details of the study design, sampling procedures, interview response rates, examination procedures, and quality controls have been described previously.[7,8] Physical assessments in homes, work sites, and clinics were completed on 3202 (58%) of the 5489 men and women interviewed.

Blood samples were drawn on each subject using standardized protocols and were analyzed within 24 hours by the South Carolina State Laboratory, a participant in the Lipoprotein Standardization Program sponsored by the Centers for Disease Control and Prevention. Total cholesterol was analyzed using enzymatic techniques[9,10]; HDL levels were analyzed using the precipitation technique.[11]

The physical assessment examination included interviewer-measured height, weight, and circumferences of the waist and hip.[12] Body mass index was calculated as weight in kilograms divided by the square of height in meters; overweight was defined as a body mass index greater than 27.3 kg/m^2. Waist-to-hip ratio was calculated as waist girth divided by hip girth. Respondents who reported that they had not participated in any leisure-time physical activity during the previous month were defined as having engaged in no leisure-time physical activity. Education was categorized as less than high school graduate versus high school graduate or higher. A respondent who had smoked at least 100 cigarettes in his or her entire life and who currently smoked was defined as a cigarette smoker.

Descriptive statistics include ethnic-specific means and percentages of each variable, and Pearson correlation coeffi-

cients that describe the unadjusted relationship of HDL with total cholesterol, age, body mass index, waist-to-hip ratio, leisure-time physical activity, smoking behavior, and educational attainment. Ethnic-specific multivariate linear regression techniques assessed the age-adjusted differences in mean HDL between levels of selected characteristics and the independent associations of age, body mass index, waist-to-hip ratio, leisure-time physical activity, educational attainment, and smoking behavior with HDL levels. All statistical procedures were implemented with SAS.[13]

Results

Although they had a younger mean age than White women in this population, Black women had significantly higher ($P < .001$) levels of HDL, body mass index, and waist-to-hip ratio, and a greater proportion of them were overweight (Table 1). There were also significantly higher proportions of Black women reporting no leisure-time physical activity and low educational achievement than White women, but similar proportions of both groups were current smokers.

In both groups, HDL had a statistically significant inverse correlation with body mass index and waist-to-hip ratio, a significant direct correlation with total cholesterol, but no relation with age (Table 2). No leisure-time physical activity, less than 12 years of education, and current cigarette smoking were significantly inversely correlated with HDL in White women only. After controlling for age, statistically significant differences ($P < .05$) in mean HDL levels were observed between weight categories in both groups and between levels of leisure-time physical activity, education, and smoking among White women only (Table 3).

In multivariate linear regression, both body mass index and waist-to-hip ratio were independently associated with HDL among both groups (Table 4). In addition, cigarette smoking and low educational attainment were inversely associated and age was positively associated with HDL in White women only. Although antihypertensive medication can

affect certain lipid levels,[14] results were unchanged after excluding the 24% of Black women and 17% of White women who were taking such medicines.

Discussion

The purpose of this study was to examine the correlates of HDL in Black and White women. In the US population,[15] important correlates of higher levels of HDL include the female gender, African-American ancestry, and alcohol consumption. Smoking and body mass index had strong inverse relationships with HDL levels. Less strongly related were age, years of education, and high levels of physical activity. Sprafka et al.[16] also showed similar results in women with the use of exogenous hormones and beta-blockers identified as additional correlates. However, these studies did not include measures of body fat distribution, which have been shown in clinical studies to be important predictors of HDL.[17]

That body mass index had a significant inverse relationship to HDL in both groups of women in this and other studies is interesting, considering the much greater prevalence of overweight[18,19] yet higher levels of HDL[15] in Black women. Our results underscore possible biological and/or environmental differences between Black and White women, which would account for the observed differences in body composition, body weight, and body fat distribution. Body fat distribution is an independent predictor of risk for coronary heart disease.[3,20] As the most sensitive measure of body fat distribution,[21] waist-to-hip ratio has been shown to be a strong inverse correlate of HDL among older men[22] and young adults.[23] In the present investigation of women, waist-to-hip ratio correlated inversely with HDL.

In univariate analyses, lack of physical activity was inversely associated with HDL only in White women. Compared with White women, Black women were more likely to report no leisure-time physical activity. In the final multivariable models, lack of leisure-time physical activity failed to have any significant impact on HDL. This can be partially explained by the correlation between physical activity and measures of body fat and by the significant effects that body composition and body fat distribution have on lipoprotein lipid levels.[24] Cross-sectional data from Coon et al.[25] suggest that the best predictor of HDL is body composition and not physical activity per se or measured physical fitness. Therefore, our failure to see a persistent relationship between leisure-time physical activity and HDL is most likely owing to the overriding effects of body composition differences in our populations and especially in the Black women, a disproportionate number of whom had body mass index levels greater than 27.3 kg/m^2. Another possible explanation may be a lack of sufficient power because of the disproportionately smaller number of Black women compared with White women in our study.

In White women of the current study, plasma HDL increased with increasing educational attainment. In contrast, an inverse relationship between HDL and education that did not reach statistical significance was observed among Black women. This may also be owing to inadequate numbers of Black women in our study. However, these findings are similar to those found by Freedman et al.[26] and Wilson et al.[27] for Black men, whose lower educational attainment was associated with higher plasma levels of HDL. Our results support a role for educational attainment in determining risk status for coronary heart disease.[28]

In summary, this study demonstrates that the most powerful correlates of HDL for Black and White women are body size and body fat distribution, with cigarette smoking and educational attainment serving as moderate predictors of HDL for White women only. These analyses demonstrate the need for investigation of the possible biological and/or environmental differences between White and Black women with regard to the correlates of lipoprotein lipids. Also needed is exploration into the mediating role of body composition in determining lipoprotein lipid levels. □

Cancer Screening among African-American Women: Their Use of Tests and Social Support

ABSTRACT

This study examined associations between social ties (as measured by the Social Network Index), instrumental and emotional support, and the use of three female cancer screening tests: mammography, cervical smear, and clinical breast examination. Data were taken from a household survey of 670 African-American women living in northern California in 1986. In multiple logistic regression models, Berkman's index was associated with increased use of mammography but not with the use of cervical smear or clinical breast examination. Instrumental and emotional support measures were not significant. These results suggest that social networks may have a role in early cancer detection. (*Am J Public Health.* 1994;84:101–105)

Soo Hyang Kang, DrPH, Joan R. Bloom, PhD, and Patrick S. Romano, MD, MPH

Introduction

One explanation of why some people seek preventive care, such as cancer screening, is that their social ties may provide the necessary support or encouragement. Previous studies have produced conflicting results on how social ties are related to the use of preventive health services. Social ties have been positively associated,[1–5] not associated,[6] or negatively associated with preventive health behavior or services[7,8] in different published reports. Comparisons of these studies are problematic because of small sample sizes and different definitions of social ties and outcome measures. Few studies have explored associations between social ties and the use of preventive health services among African Americans.[9,10] The present study examines social ties (as measured by a social network index) and instrumental and emotional support and their relationships with the use of cancer screening tests among African-American women.

Methods

Self-reported use of mammography, cervical cytology, and clinical breast examination was investigated in a two-stage random household sample of the African-American population of Oakland and San Francisco, Calif, in 1986.[7,11] First, 100 census blocks in which African Americans constituted 25% or more of the population (based on 1980 census data) were randomly selected from each of the two cities. Second, households were randomly selected within these blocks. The Kish[12] procedure was used to randomly select one respondent 20 years of age or older from each African-American household, and face-to-face interviews were conducted. The response rates for Oakland and San Francisco were 67.6% and 69.1%, respectively. Of the 1137 respondents, 467 were men, who were excluded from the current study. Consistent with census data, 59% of the respondents were women (n = 670).

* $P < .05$ (two-tailed test).

The survey instrument included questions on previous use of six cancer screening tests, social ties, instrumental and emotional support, health status, a source of primary care, insurance, and sociodemographic characteristics. Since the purpose of this study was to examine the use of female cancer screening tests as a preventive measure, only respondents who had a screening test as part of a routine examination were classified as having received the test; other respondents were classified as not having received the test. The three dependent variables in the study were whether or not the subject received (1) mammography, (2) cervical smear, and (3) clinical breast examination.

Social ties were measured by a slightly modified version of Berkman and Syme's Social Network Index. This index includes four different measures of social ties: marital status, number of relatives and friends, church participation, and participation in other organizations.[3] Possible scores range from a low of one (representing those with the fewest social ties) to a maximum of four (representing those with the most social ties). Emotional and instrumental support measures were adapted from Seeman and Syme.[13]

Respondents' self-reported health status, a source of primary care, health insurance coverage, age (along with a quadratic term to adjust for nonlinearity), and educational status were included as covariates because they have been previously related to the use of preventive health services.[7,14,15]

Multiple logistic regression models were estimated to determine whether social ties influenced the use of cancer screening tests after potential confounders were controlled. All female respondents were included in the model for routine cervical smear and routine clinical breast examination (n = 670). For routine mammography, only female respondents 35 years of age or older (n = 418) were included, since mammography is generally not recommended for women less than 35 years old.[16,17]

Results

Since the samples from the two cities were almost equal in size and showed similar demographic characteristics, they were combined for purposes of these analyses (Table 1). The results of the bivariate analyses between the Social Network Index and the use of cancer screening tests are presented in Table 2.

In a multiple logistic regression analysis for routine mammography (Table 3), the Social Network Index remained a significant explanatory variable after health status, age, age squared, education, having health insurance, and having a primary care source were controlled. The adjusted odds ratio (OR) was 1.3 for each additional level of the index (95% confidence interval [CI] = 1.03, 1.70), suggesting that women with larger social networks were more likely to have had a routine mammogram than those with smaller networks.

The Social Network Index was not a statistically significant predictor of the use of cervical smear (adjusted OR = 1.2, 95% CI = 0.9, 1.7) or clinical breast examination (adjusted OR = 1.1, 95% CI = 0.9, 1.5) in these analyses. The instrumental and emotional support measures were tested in separate logistic models with the same control variables. Neither of these support variables was significantly associated with the use of mammography, cervical smear, or clinical breast examination.

Discussion

Women with more social ties were more likely to have had a routine mammogram than were those with fewer social ties, even after health status, age, education, type of health insurance, and having a primary care source were controlled. The lack of any associations between the other two tests and the selected predictors may have been due to insufficient statistical power, since almost all women in this study had a cervical smear or a clinical breast examination. Another explanation may be the location of the screening. A mammogram generally requires a referral to a different facility, while both cervical smears and clinical breast examinations are performed during routine physical examinations. Social networks may be important not only in encouraging an initial

visit to the doctor's office but in following through with scheduling and receiving the test and in gaining acceptance for the doctor's recommendation.[14]

No associations were found between the instrumental and emotional support measures and the use of cancer screening tests. These measures were based on a small number of items and may not have captured the qualitative features of supportive social interactions. Alternatively, functional aspects of social support may be less important than the structural features measured by the Social Network Index.

Whether unmeasured factors, such as prior illness or personality characteristics, influence both social networks and use of cancer screening tests is not clear in these data. Chronic illness may lead to social isolation as people become unable to maintain personal contacts; it may also increase the use of diagnostic medical procedures. Our study findings are limited to the use of cancer screening tests among African Americans; additional studies are needed to determine whether these results apply to other ethnic and racial groups. Despite these limitations, this study suggests that African-American women with smaller social networks are less likely to receive a mammogram than are African-American women with larger networks. Interventions that use social ties may, therefore, have a role in promoting early cancer detection. □

Promoting Mammography Use through Progressive Interventions: Is It Effective?

Eunice S. King, PhD, RN, Barbara K. Rimer, DrPH, Janet Seay, MPH, Andrew Balshem, BA, and Paul F. Engstrom, MD

ABSTRACT

This study evaluated interventions implemented with women in a health maintenance organization who had not utilized their annual free mammogram referral 45 days (step 2) and 95 days (step 3) after its mailing. The step 2 evaluation compared mammography utilization for women randomly assigned to receive a brief reminder letter or no reminder: 42% of the reminder group vs 28% of the control group obtained mammograms. The step 3 evaluation compared utilization for women randomly assigned to receive a second reminder, a letter suggesting a preventive office visit, or telephone counseling: 29% of those who received telephone counseling, 14% of those who received a letter, and 12% of those who received a second reminder obtained mammograms. (*Am J Public Health.* 1994;84:104–106)

Introduction

Although regular mammograms can reduce mortality from breast cancer by about 34% in women aged 50 and older,[1,2] most American women are not getting them.[3–5] The purpose of this study was to evaluate interventions developed for an individual practice association–model health maintenance organization's (HMO's) annual breast cancer screening program directed at more than 50 000 women aged 50 through 74 years.[6] Interventions were implemented in three steps, beginning with a breast cancer information packet (step 1) containing a free mammogram referral (Table 1). A central office tracked mammography use through radiology reports and identified women eligible for subsequent interventions.

This study assessed whether a brief reminder (step 2) was more effective than no reminder and compared the relative impact of three different interventions—telephone counseling, a second reminder letter, and a letter suggesting a preventive office visit—in motivating still nonadherent women to get mammograms (step 3).

Methods

Procedures

For the step 2 and step 3 intervention evaluations, two mutually exclusive samples were used. So that both interventions could be completed within the same time period, thereby minimizing effects of secular events, women for the step 3 evaluation were selected first because of step 3's longer follow-up period (185 days vs 95 for step 2).

Step 2 evaluation. At the time their annual packet was mailed (step 1), 2127 women were randomized to a no-reminder or reminder group. Women in the latter group who did not obtain a mammogram within 45 days of the packet mailing were mailed a brief reminder letter. Ninety-five days after the packet mailing, a brief telephone survey was conducted to assess the women's mammography status at days 45 and 95. Of the original 2127 women, 745 were eligible for evaluation; of these, 21% could not be contacted during the allotted time interval, 19% had already had their mammograms, and 1% refused.

Step 3 evaluation. An annual packet (step 1) was mailed to 2123 women who constituted the initial sample and a step 2 reminder was sent to women without a mammogram report. Ninety days after the packet mailing, we attempted to survey 1265 women without a mammogram report to verify their mammography status. Of these, 25% could not be contacted during the 1-week eligibility evaluation window, 25% had already had mammograms, and 2% refused. Thus, 598 eligible women were randomized to one of three interventions: (1) a second reminder letter (n = 198); (2) a preventive office visit letter, urging women to have a checkup (n = 198); and (3) telephone counseling (n = 202, with 173 completed calls).

A telephone counseling intervention, based on the health belief model,[7] the transtheoretical model of behavior change,[8] and the conflict model of decision making,[9] was developed to help women overcome their personal barriers to mammography. The counseling content was guided by scripted responses to 26 potential barriers.[6,10–12]

Study Measures

The step 2 and step 3 telephone surveys, designed to obtain demographic data and the date and location of the woman's most recent mammogram, were conducted by professional interviewers in less than 5 minutes. The outcome variable was whether or not women obtained mammo-

grams following the interventions (between 46 and 95 days after the packet mailing for women in the step 2 evaluation and within 90 days following the intervention for women in step 3). Only women whose self-reports of mammography were verifiable by medical records were considered adherers.

Data Analysis

For both the step 2 and step 3 evaluations, chi-square tests of significance were used to assess relationships between study group and adherence and demographic characteristics and adherence. In the step 2 analysis, possible confounding by marital status and education was controlled by including these variables along with study group in a logistic regression analysis. In the step 3 analysis only study group was included, because no demographic characteristic was related to adherence.

Results

Most women in the step 2 and step 3 evaluations were married, employed, between 55 and 75 years of age, and had at least a high school education; 12% to 16% were African Americans (Table 2). There were no significant differences in the demographic characteristics of the study groups.

The step 2 evaluation found that 42% of the reminder group and 28% of the no-reminder group ($P < .001$) had obtained mammograms within the 46- to 95-day period (Table 3). As Table 4 shows, women who received the step 2 reminder were more likely to have had a mammogram than those who did not (odds ratio [OR] = 1.9). Women with more than a high school education were more likely than those with less education to have had a mammogram (OR = 2.0), and married women were more likely than unmarried women to have had one (OR = 1.7). There were no significant interactions.

In the step 3 evaluation, 29% of the women in the telephone counseling group obtained subsequent mammograms, compared with only 12% of those in the second reminder group and 14% in the preventive office visit letter group ($P < .001$). The odds of having had a mammogram were three times as high for women in the telephone counseling group as for women in the second reminder group, whose odds were similar to those of women in the preventive visit letter group (see Table 4).

Discussion

In this study, a simple, inexpensive letter ($0.91 per success) resulted in significant improvement in mammography use 46 to 95 days after the annual packet mailing. For women who were still nonadherent, telephone counseling, compared with the letters, nearly doubled the odds of getting a mammogram. The cost per success for telephone counseling ($4.92), although higher than for the second reminder ($2.73) or preventive letter

TABLE 4—Logistic Regression Analyses: Variables Associated with Having a Mammogram

	Odds Ratio	95% Confidence Interval	P
Step 2 evaluation			
Reminder vs no reminder	1.9	1.4, 2.6	.001
Married vs not married	1.7	1.2, 2.4	.003
High school graduate vs did not complete high school	1.4	0.9, 2.1	.2
More than high school vs did not complete high school	2.0	1.2, 3.2	.006
Step 3 evaluation			
Phone counseling vs second reminder	3.0	1.8, 5.1	< .001
Preventive visit letter vs second reminder	1.2	0.7, 2.2	.48

($3.68), is still reasonably inexpensive. Telephone counseling conducted by volunteers, rather than professionals, may reduce the cost of this intervention and should be evaluated in future studies.

The generalizability of this study's results is limited by the fact that the study was conducted within an HMO population for whom the cost barrier was removed by the annual free mammogram referral. In addition, because there was no control group for the step 3 evaluation, we cannot separate the effect of the telephone survey to assess status from the effect of the interventions. However, it is likely that the potential impact of the telephone survey would be distributed equally across the three groups within the step 3 evaluation sample. In future studies other variables, such as women's underlying knowledge, attitudes, and current preventive health practices, should be assessed and the interventions should be tested in other (non-HMO) settings. □

The Use of Mammography Vans by Low-Income Women: The Accuracy of Self-Reports

Susan Etzi, MD, MPH, Dorothy S. Lane, MD, MPH, and Roger Grimson, PhD

ABSTRACT

The objective of this study was to determine the accuracy of self-reports of mammography use by low-income women. Mammography van records were used to verify self-reports of mammography use in the past year by women aged 50 through 75 years who had visited five community health centers (n = 237). Van records verified mammography use for 99% of these women (82% within the previous year and 98% within the past 2 years). Forty percent of those with van records who reported both the month and year of the mammogram were accurate. Inaccurately reported dates were more frequently after (74%) rather than before (26%) the actual date. These findings indicate that self-reports of mammography use by low-income women are generally reliable. (*Am J Public Health.* 1994;84:107–109)

Introduction

National objectives and initiatives specifically target low-income women for interventions designed to increase mammography use because there is evidence of particularly low utilization rates among the disadvantaged.[1–3] Methods of measuring the effectiveness of interventions designed to increase mammography use are needed. There are reports of a high validity of women's self-reports in health maintenance organization (HMO)[4,5] and community[6] settings. We examined whether this is also true for a less educated, lower-income population that visits community health centers.

The Suffolk County Department of Health Services funds five health centers in the intervention area of our community-based breast cancer project.[7] Beginning in January 1988, mammography was provided at each of the health center sites, initially through a county contract with a private mammography van service and subsequently (beginning February 1990) through a mammography van purchased by the Department of Health Services.

Methods

A telephone survey was conducted in 1990 of a random sample of women aged 50 through 75 years from computer files of women who had visited one or more of the five health centers for any reason within the previous year. The survey methodology has been described in detail elsewhere.[8] Sixty-three percent of the original sample completed the survey. Lack of a telephone number was the most common reason for failure to contact the women: 19% of the sample did not have telephones or had unknown or incorrect telephone numbers. Of the women with apparently correct telephone numbers, who therefore could potentially be contacted, 75% completed the survey.

Of the 844 women interviewed, 806 were included in the analysis (38 were excluded because of a prior history of breast cancer or because they were not in the age range of 50 through 75 years). The socio-demographic characteristics of the 806 respondents have been described elsewhere; they were consistent with a disadvantaged population.[8] The survey instrument included questions about whether the respondent had ever had a mammogram, when and where she had her last mammogram, and who paid for it. The date of the last mammogram was recorded by month (or season if the month could not be recalled) and by year.

The validation study of women's self-reports was limited to the 237 women who indicated that they had had a mammogram in a van in the previous year. Matches between survey and van records were double-checked by hand to identify incorrect or missed matches due to spelling errors and for accuracy of match by patient's name, address, date of birth, and clinic site where patient received her usual medical care. The patient's estimated date of her last mammogram and the actual date recorded in the van records were compared. Reports of a mammogram in the previous year were verified by determining whether the actual date of the van mammogram was no more than 12 months prior to the survey month. Since the van files covered a period longer than 1 year, occasionally a patient had a record of more than one mammogram in the van files. The date on which the woman was surveyed by telephone was used to compute the 12-month period of interest, thereby determining which mammogram record was to be included in the study.

Results

Mammography Use

Of the 806 respondents, 631 (78%) reported ever having had a mammogram.

At the time of the study, all authors were with the Department of Preventive Medicine, School of Medicine, State University of New York at Stony Brook.

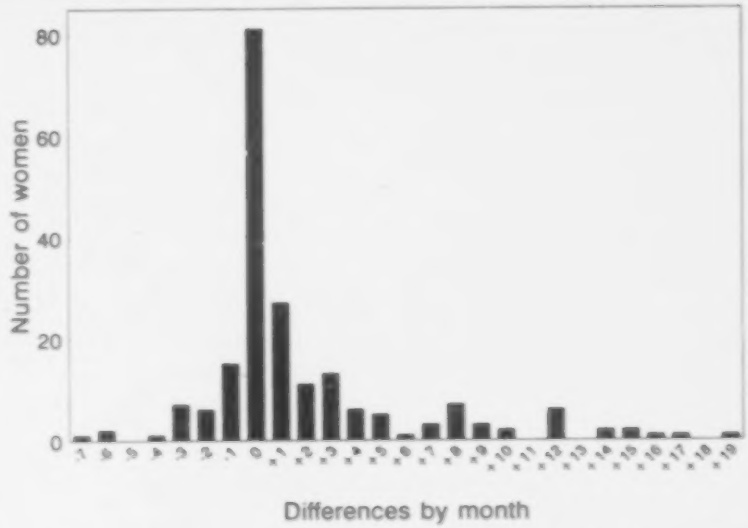
TABLE 1—Number of Women for Whom Documentation Supported the Accuracy of Self-Reported Mammography

Actual Date of Mammogram	No. (n = 237)	%
Within past 12 mo	194	81.9
Within past 13–24 mo	38	16.0
Within past 25–36 mo	3	1.3
No record found	2	0.8

TABLE 2—Number of Women Who Recalled Mammography Date Accurately, by Time since Mammogram

Time Since Mammogram	n	Estimated Date vs Real Date			Mean Difference[a]	Median Difference[a]
		No. Earlier	No. Same	No. Later		
≤3 mo	51	7	35	9	−2.24	0
>3–6 mo	54	12	24	18	1.15	0
>6–12 mo	71	13	21	37	45.92	30
>12 mo	28	0	0	28	297.86	288.5
Total	204	32	80	92		

[a]Difference = estimated date minus real date in months.



Note. 0 = agreement by month and year (accurate); − = estimated date before actual date; + = estimated date after actual date.

FIGURE 1—Differences between actual and estimated months of mammogram (n = 204).

Three hundred seventy-eight (47%) reported having had a mammogram in the previous year, and the majority of these (237, or 63%) gave a van as the location of the mammogram. Twenty percent said they had had the mammogram at a radiologist's or doctor's office; 12% at a clinic, health center, or HMO; and 6% at a hospital.

Accuracy of Reporting

Van records were obtained for 99% of the women who reported having had a mammogram in a van in the previous year, and 82% of these women had documentation that the mammogram was actually performed in that year (Table 1). An additional 16% had documentation of a van mammogram within the past 13 through 24 months, and 1% had documentation of a van mammogram within 25 through 36 months. No documentation was found for 2 women (0.8%).

Comparisons between self-reports and van records for month and year of the mammogram showed that 81 (40%) were in agreement, 124 (61%) were within 1 month, 161 (79%) were within 3 months, and 197 (97%) were within 1 year. For 7 (3%) of the women, the actual date differed from the self-reported date by more than a year. For the 123 women who were inaccurate in their recall, the self-reported date was more frequently after the actual date of mammography (for 91 women, or 74%) than prior to the actual date (for 32 women, or 26%). The difference between the actual and estimated dates of mammography in number of months is displayed in Figure 1.

Accuracy of recall diminished with time since the last mammogram,* as detailed in Table 2. The majority of women who had had a mammogram within the 3 months prior to being surveyed were accurate in their recall, whereas the majority of women who had had their mammograms from 6 to 12 months previously believed that they had had the mammogram later than the actual date. This was also true for all of the women who had actually had the mammogram more than a year prior to their date of recall.

Discussion

The results of our study indicate that the self-reports of low-income women visiting community health centers are a reliable source of data on mammography use in the past year. Van records verified mammography use for 99% of the women studied (82% within the prior year and 98% within the past 2 years). For 40% of the women who reported both the month and year of the mammogram, the dates corresponded to van records. The remaining women, who were inaccurate in recalling the date, were more likely to believe that they had had the mammogram more recently than they actually did (74%) rather than earlier. This memory effect is known as forward telescoping.[10,11] Accuracy in estimating the date of the mammogram declined with time,* and more than 6 months after having the mammogram most women (66%) believed that they had had it later than the actual date. More than 12 months after the mammogram, all women believed that they had had it later than the actual date. If the women were to rely on their own recall in scheduling subsequent mammograms, the time between mammograms would extend beyond the recommended interval. This suggests the desirability of using health center–initiated patient reminders to prompt timely scheduling of annual mammography.

A 94% accuracy rate for self-reports of mammography use in the past year

among women enrolled in an independent practice association HMO was reported by King et al.[4] Our project found that 88% of the self-reports of mammography use in the past year among women enrolled in a staff model HMO were confirmed by medical records.[5] This proportion is close to the 82% rate we found for the self-reports of women attending health centers, despite statistically significantly higher income and education in the HMO group than in the health center group. The women in the HMO also tended to underestimate rather than overestimate the time since their last mammogram.[5]

To explore the effectiveness of interventions designed to accomplish the Year 2000 objectives, it is important to be able to measure changing mammography screening practices among low-income women. The results of our validation study indicate that surveys of such women provide reliable data on mammography use in the previous year. □

WFPHA International Congress on Health, Economics, and Development

The World Federation of Public Health Associations (WFPHA) will hold its Eighth International Congress, "Health, Economics, and Development: Working Together for Change," December 5 through 9, 1994, in Bali, Indonesia. Join health practitioners, policymakers, administrators, development workers, economists, researchers, and many others from governments, international organizations, and private groups in this exciting and ambitious event. Examine the linkages among health, economics, and development. Develop an action agenda to integrate health concerns with economic and development policies.

The WFPHA is a nongovernmental organization composed of national public health associations from 41 countries around the world. WFPHA congresses are held every 3 years and are cosponsored by the World Health Organization and the United Nations Children's Fund. This congress will be hosted by the Indonesian Public Health Association. Participation is open to all. The official language of the congress is English.

For further information and abstract forms, contact WFPHA Secretariat, c/o American Public Health Association, 1015 15th St NW, Suite 300, Washington, DC 20005 USA; fax (202) 789-5681. The deadline for abstract submission is *May 15, 1994.*

Screening for Childhood Lead Poisoning: A Cost-Minimization Analysis

ABSTRACT

Decision analysis was used to compare the costs of three screening strategies for childhood lead poisoning: (1) venipuncture; (2) capillary sample with venipuncture confirmation if the blood lead level is elevated; (3) stratification by risk, with venipuncture for high-risk children and capillary sample for low-risk children. Under baseline conditions, the cost of screening by the venipuncture, stratification, and capillary strategies is $22, $25, and $27, respectively. Venipuncture remains the least expensive strategy unless the cost of venipuncture is more than three times that of capillary sampling. The annual cost of a national lead screening program that uses a single venipuncture sample would be $352 million. Initial screening with a capillary sample would cost $432 million, 23% more than venipuncture. (*Am J Public Health.* 1994;84:110–112)

Introduction

Lead poisoning is one of the most common and preventable illnesses of childhood. It is estimated that one of every six United States children has an elevated blood lead level (≥0.72 μmol/L [15 μg/dL]), which is associated with adverse health effects.[1] The 1991 Centers for Disease Control (CDC) guidelines for lead screening differ significantly from earlier versions.[2] The CDC now recommends universal blood lead screening for all US children under age 6 years, except for children in communities that can demonstrate that they do not have a childhood lead poisoning problem. A blood lead level is now recommended as the primary screening test, rather than the erythrocyte protoporphyrin level, because erythrocyte protoporphyrin screening is not sufficiently sensitive to detect most children with blood lead levels above 1.21 μmol/L (25 μg/dL).[3–5]

The guidelines advise that a level of 0.72 μmol/L (15 μg/dL) or greater from a capillary sample should be confirmed by a venous sample because capillary samples may be falsely positive. Between 22% and 29% of capillary samples were found to be falsely elevated when the blood lead level of concern was 1.93 μmol/L (40 μg/dL),[6] so the false-positive rate is likely to be at least as high if the threshold is lower. However, obtaining specimens by venipuncture is more difficult than capillary sampling, and initial screening by venipuncture is not widely used.[7] The objective of this study was to compare the costs of universal blood lead screening by different strategies.

Methods

We used decision analysis[8,9] to compare the costs of the following three strategies: (1) initial screening with a venipuncture specimen; (2) initial screening with a capillary specimen, with venipuncture confirmation if the blood lead level was ≥0.72 μmol/L (15 μg/dL); and (3) stratification according to risk level as determined by questionnaire and then screening high-risk children with a venipuncture specimen and low-risk children with a capillary specimen, with venipuncture confirmation for blood lead levels of ≥0.72 μmol/L (15 μg/dL).

Baseline estimates of variables in the model were obtained from the medical literature. Costs were obtained from the 1990 rate book of The Children's Hospital, Boston, Mass.[10] This rate book lists the same cost ($3) for phlebotomy by both venipuncture and capillary sampling. However, in the baseline analysis we estimated that the cost of phlebotomy by venipuncture was twice as expensive as capillary sampling to more closely simulate the national experience. Costs rather than charges were used for this analysis, because costs more accurately reflect true resource use. SMLTREE software[11] was used to construct and evaluate the decision tree. Sensitivity analysis was used to explore the effect of changing variables over a range of clinically reasonable values (Table 1).

Results

Given baseline prevalences and costs, initial screening of all children with a venipuncture specimen cost $22 per child, and screening by the stratification and capillary strategies cost $25 and $27, respectively.

Sensitivity analysis (Table 2) demonstrated that the venipuncture strategy was the least expensive strategy over almost the entire range of variables indicated in

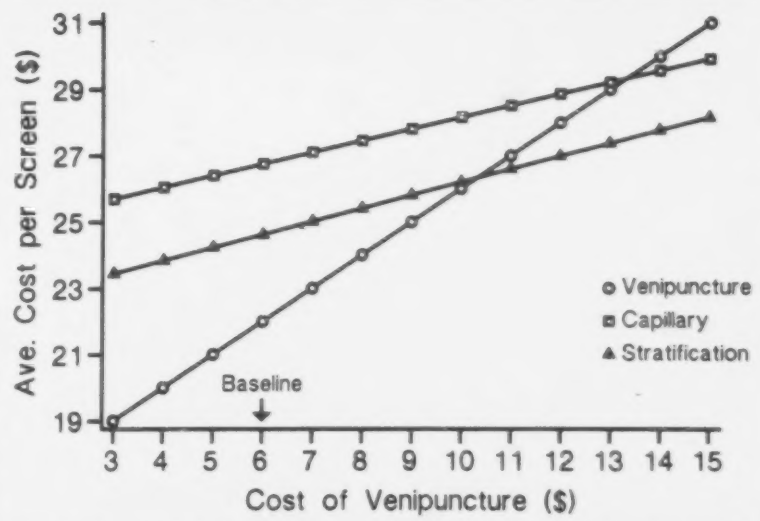
TABLE 1—Baseline Prevalence and Cost Estimates in the Model and Ranges Tested in Sensitivity Analysis

	Baseline (Range)	Reference
Prevalence of blood lead levels of ≥ 0.72 µmol/L (15 µg/dL) for all children	17% (1–50%)	1
Prevalence of blood lead levels of ≥ 0.72 µmol/L (15 µg/dL) for low-risk children	7.5% (0.5–10%)	1
Percentage of high-risk children	16% (1–50%)	1
False-positive rate	22% (5–50%)	6
Cost of phlebotomy for venipuncture specimen	$6 ($3–15)	10 and authors' estimate
Cost of phlebotomy for capillary specimen	$3 ($1–10)	10
Cost of blood lead analysis	$16 ($5–75)	10
Cost of erythrocyte protoporphyrin analysis	$0 ($0–15)	10

TABLE 2—Sensitivity Analysis of Selected Variables: Cost per Child According to Screening Strategy

	Value Tested	Cost of Screening Strategy, $		
		Venipuncture	Stratification	Capillary
Cost of blood lead analysis (baseline value = $16)	$5	11	11	12
	$35	41	48	52
	$75	81	97	107
Cost of phlebotomy for venipuncture specimen (baseline value = $6)	$3	19	23	26
	$9	25	26	28
	$15	31	28	30
Prevalence of blood lead levels of ≥ 0.72 µmol/L (15 µg/dL) (baseline value = 17%)	1%	22	24	24
	5%	22	24	25
	30%	22	25	29
Cost of phlebotomy for venipuncture specimen ($10) and prevalence of blood lead levels of ≥ 0.72 µmol/L (5%) (baseline values = $6 and 17%, respectively)		26	25	26
False-positive rate (baseline value = 22%)	5%	22	22	24
	35%	22	27	29
Cost of erythrocyte protoporphyrin analysis (baseline value = $0)	$5	27	31	34
	$10	32	37	40
	$15	37	43	47

Note. See Table 1 for baseline values for all variables.



Note. Venipuncture is the least expensive strategy unless the cost of venipuncture exceeds $10 per sample. The capillary strategy is more costly than the venipuncture strategy if the cost of venipuncture is less than $13 per sample. In the baseline analysis, the costs of venipuncture and capillary sampling were estimated at $6 and $3 per sample, respectively. Ave. = average.

FIGURE 1—The cost of lead screening plotted as a function of the cost of venipuncture.

Table 1. Because venipuncture is the final step in all the screening strategies, and because the cost of laboratory analysis is the same for capillary and venous samples, the venipuncture strategy is the least expensive strategy unless the cost of venipuncture phlebotomy is more than three times higher than the cost of capillary sampling (Figure 1).

As the prevalence of elevated blood lead levels decreased from 17% (baseline) to 5%, the cost of the venipuncture strategy was unchanged ($22). However, the cost of the stratification ($24) and capillary ($25) strategies decreased, reducing the added cost of these strategies compared with the venipuncture strategy. Under conditions of low prevalence (5%) and a high cost of venipuncture ($10), the stratification strategy ($25) became less expensive than either the venipuncture ($26) or capillary ($26) strategies.

If only 5% of the capillary samples are falsely elevated, the cost of screening by venipuncture would be the same as the cost of the stratification strategy ($22), but would remain less expensive than the capillary strategy ($24).

In our baseline analysis, we assumed that only blood lead analysis would be performed. However, erythrocyte protoporphyrin levels are often used as an adjunctive test for managing childhood lead poisoning. If erythrocyte protoporphyrin testing ($10) is included in the screening strategies, the venipuncture strategy ($32) would become even less expensive relative to the stratification ($37) and capillary ($40) strategies.

Discussion

This analysis demonstrates that a single venipuncture sample is the least

costly method of universal screening for childhood lead poisoning. The CDC recommends annual screening for children at low risk for lead poisoning and screening at 6-month intervals for high-risk children. Based on the US Public Health Service estimates,[1] 16 million blood lead screening tests on children under age 6 years will be required annually. According to our model, a lead screening program that uses a single venipuncture sample would cost $352 million per year. The annual costs of screening by the risk stratification and capillary strategies would be $400 million and $432 million, respectively, a 14% to 23% increase over the cost of screening with a single venipuncture sample.

Sensitivity analysis demonstrated that the venipuncture screening strategy is the least expensive approach over a wide range of prevalences, false-positive rates, and costs. For populations with a low prevalence of elevated blood lead levels, initial screening with capillary specimens may appear to be a more attractive strategy, at minimal additional average cost. However, because of the large numbers of screening samples required in areas of even moderate prevalence and the high rate of necessary rescreening because of false-positive results, the overall additional annual expenditure generated by this approach is considerable.

Issues of time, availability of skilled pediatric phlebotomists, convenience, and child/parent preference for the method of sampling were not considered in this analysis. Although initial screening by capillary sample may appear to be simpler than initial screening by venipuncture, that may not be true if a confirmatory sample by venipuncture is required.

This analysis indicates that methods for childhood lead screening differ substantially in cost. Better data are needed regarding the false-positive rate by capillary sampling now that the blood lead level requiring rescreening is 0.72 μmol/L (15 μg/dL). In addition, improved capillary sampling techniques that eliminate the need for venous confirmatory samples are needed. However, based on current information and existing techniques, a screening strategy that uses a single venipuncture sample can reduce the cost of screening for childhood lead poisoning. □

Who Participates in Cardiovascular Disease Risk Factor Screenings? Experience with a Religious Organization–Based Program

Barbara L. Wells, PhD, Charles C. Brown, PhD, John W. Horm, MSc, Richard A. Carleton, MD, and Thomas M. Lasater, PhD

ABSTRACT

Adult members who declined participation in cardiovascular disease risk factor screenings offered at religious organizations were randomly selected and asked to participate in screenings at their homes. Relationships between screening participation and sociodemographic, behavioral, and physiological measures were examined. Age, knowledge of cardiovascular disease risk factors, body mass index, current smoking status, previous report of elevated blood pressure, current diastolic blood pressure measurement, frequency of worship service attendance, and residential distance from the religious organization screening site were important predictors of screening response. Those with conspicuous risk factors appeared less likely to initially respond to religious organization site screening invitations. (*Am J Public Health.* 1994;84: 113–115)

Introduction

Cardiovascular diseases continue to be the leading cause of death in the United States.[1] Among their modifiable risk factors, elevated blood cholesterol and blood pressure are generally asymptomatic and present specific detection issues. Screening is essential for the identification and referral of undetected, untreated, or inadequately treated hypertensive or hypercholesterolemic people.[2,3]

One promising community setting for conducting screenings is religious organizations.[4] More than half the US population are reported to be members of an estimated 286 811 religious congregations,[5,6] and religious organization screening programs that target elevated blood pressure among Black[7–13] and White populations[14] have reported generally favorable, but not unanimous, results. Nevertheless, there have been those individuals who have chosen not to participate in such screenings.

Few studies have characterized screening nonparticipants for any of the cardiovascular disease risk factors. However, because the research that forms the context of this report was part of a multiple cardiovascular disease risk factor intervention trial testing the efficacy of religious organizations as health promotion sites, that trial presented the opportunity to examine the sociodemographic, behavioral, and physiological differences between participants and nonparticipants.

Methods

The intervention trial was conducted in 20 religious organizations randomly selected from the largest denominations in the state of Rhode Island.[15] The 10 Catholic, 5 Northern Baptist, and 5 Episcopal religious organizations are in 15 communities and have predominantly Caucasian memberships of between 250 and 5000 individuals. Approximately 10% of each organization's members aged 18 to 65 years were randomly selected for the initial screening. A letter of invitation from the pastor requested each selected member to schedule an appointment, at that person's convenience, for a free cardiovascular disease risk factor screening. At least five telephone contact attempts were made to those who did not call before a potential participant was deemed not reachable.

Ten religious organizations, proportionally representing the religious denomination distribution of participants, were selected to participate in the follow-up survey to assess nonparticipation. The nonparticipant survey was conducted during the same season as the initial screening with about 85 nonparticipants randomly selected from each organization. Trained interviewers visited the selected member's home as often as necessary to make the contact personally; the number of visits ranged from 1 to 28, with a mean of 5.9. Interviews were scheduled at the member's convenience and conducted primarily in the home; a small number of interviews were conducted at the member's

*$P < .0001$; **$P < .01$.

place of business. The interview and physiological measurements were the same as those used at the religious organization sites. All 658 respondents to the initial screenings in these 10 religious organizations were compared with the nonparticipants.

Logistic regression[16] was used to relate initial screening nonparticipation to 39 factors determined from the interview and physiological measures. These factors fell into seven categories, including sociodemographic characteristics (gender, education, employment status, income); cardiovascular disease physiological risk factors (body mass index, cholesterol levels, systolic and diastolic blood pressure measures); respondent's activity in the religious organization (length of association, committee membership, spouse association); cardiovascular disease risk factor–related behaviors (exercise frequency, current smoking status); and cardiovascular disease knowledge and beliefs (accurate systolic and diastolic blood pressure knowledge, self-rating of cardiovascular disease risk).

A series of increasingly stringent regression analyses[17] were conducted in four stages. First, separate analyses were conducted for each of six predictor variable categories; sociodemographic variables were not analyzed at this stage. Statistically significant categories ($P < .05$) were then included in the second stage to determine the best combination of predictors. In the third stage, the significant predictors were combined with sociodemographic variables. The final stage determined the combination of significant predictors ($P < .05$) that accounted for the largest amount of variation in screening participation.

Results

Of 3277 eligible subjects randomly selected for the initial screening from the membership lists of 20 religious organizations, 1167 agreed to participate. Participation rates in the individual organizations ranged from 17% to 43%. We randomly selected 847 persons who refused the initial screening to request participation in the second screening. Those who moved, died, were no longer members of the religious organization, or could not be found totaled 171 (20%). Of 676 persons contacted, 326 (48%) agreed to participate; the most commonly reported reasons for refusing the second screening were a too-busy schedule or a schedule conflict (18%), or disinterest (15%).

Sociodemographic and health characteristics of initial screening participants and nonparticipants are presented in Table 1. Because these factors and others are interrelated, multivariate logistic regression was used to determine the statistically important factors. The final regression model composition is given in Table 2. Significant determinants of participa-

tion in the initial religious organization screening fall into three primary categories: (1) religious organization activity as measured by worship service attendance; (2) convenience as measured by distance from the screening site; and (3) health characteristics as measured by current smoking status, body mass index, past high blood pressure, cardiovascular disease risk factor knowledge, current diastolic blood pressure, and age. No significant interactions were found between these factors and either age or gender, nor between current blood pressure level and past high blood pressure status. No variables from the categories of social context (e.g., supportiveness of family and friends) or preventive health behaviors and beliefs (e.g., frequency of physical examinations, self-rated health) were found to be statistically significant in the final model.

Discussion

Cardiovascular disease risk factor screening in religious organizations appeared to appeal more to older members who were more active in and resided closer to the organization. Religious organization screenings also attracted more participants with elevated blood pressure readings, 55% of whom reported previous high blood pressure. The proportion of participants with elevated measures exceeds the 11% to 12% detected in random sample households of the same age distribution in communities adjacent to the study religious organizations (T. M. Lasater, PhD, personal communication, March 1993).

About 87 (27%) nonparticipants also reported previous high blood pressure, but current diastolic and systolic blood pressure measured within normal range. It is plausible that these individuals had less incentive to participate in a screening program if they were already being successfully treated for hypertension. The final regression model results did not statistically differ when this 27% was excluded from the analysis.

Because cardiovascular disease screening response rates are so varied in secular organizations—for example, they may be as low as 9%[18] or as high as 81%[19] in work sites—we cannot conclude that the rates in religious organizations are better or worse. What is known is that religious organizations may lack precise denominators because membership lists can be incomplete and outdated; ours were rendered reasonably accurate only after an extensive investment in time, particularly among those organizations with large memberships or loose membership criteria.

Screening participation appeared to increase with higher levels of cardiovascular disease risk factor knowledge, supporting the notion that educational/promotional campaigns be a prerequisite to the conduct of religious organization screenings. The prevalent cardiovascular disease risks of reluctant participants (i.e., smoking and higher body mass index) suggest that such persons are likely to require different intervention strategies to encourage screening participation than their more health-conscious counterparts. Thus, if these religious organizations wish to reach reluctant, at-risk persons in their on-site screening catchment, they need to determine the most effective strategies to attract such persons. □

Is Cardiopulmonary Resuscitation Training Deleterious for Family Members of Cardiac Patients?

Kathleen Dracup, DNSc, RN, Debra K. Moser, DNSc, RN, Peter M. Guzy, PhD, MD, Shelley E. Taylor, PhD, and Celine Marsden, MN, RN

ABSTRACT

The purpose of the study was to determine the attitudes toward cardiopulmonary resuscitation (CPR) training and subsequent CPR use of 172 CPR-trained family members of cardiac patients. The majority (88.9%) reported positive attitudes. Only 14 (8.1%) reported feeling too responsible for their family member. One hundred and forty-one (81.9%) said that they would perform CPR if required to do so. Family members do not feel unduly burdened by learning CPR, and CPR training should be recommended to families of patients at risk for sudden cardiac death. (*Am J Public Health.* 1994;84:116–118)

Introduction

Patients with heart disease are at high risk for sudden death. Most of these events occur out of the hospital, in the individual's home.[1–3] Thus, family members are an important target for public education efforts related to reducing the time of response to a sudden-death event. Unfortunately, few family members receive cardiopulmonary resuscitation (CPR) instruction.[4] In fact, the majority of physicians and health educators are reticent to recommend CPR training for families of cardiac patients, citing fears that CPR training will be experienced as a heavy burden and that CPR may be performed inappropriately or ineffectively.[5–9] The purpose of our study was to determine CPR training attitudes, practice patterns, and incidence of CPR use in CPR-trained family members of cardiac patients.

Methods

Family members (n = 337) of patients at risk for sudden cardiac death were enrolled as part of a multicenter clinical trial designed to determine the emotional consequences of different types of CPR training. Subjects were selected from one of four hospital sites by the following criteria: (1) age 25–80 years, (2) literate in English, (3) no CPR training within the past 2 years, and (4) living with a relative at risk for sudden death by virtue of cardiac disease. They were randomly assigned to either a control group (n = 99) that did not receive CPR training or to one of three types of CPR training (n = 238). These CPR training groups were CPR training only, CPR training with the addition of an educational segment about reduction of cardiac risk factors, and CPR training followed by a social support intervention. Because there were no differences among the three CPR-trained groups on attitudes, practice, or retraining, the three groups were combined for purposes of this report.

CPR training consisted of one-person CPR taught by a clinical nurse specialist who was certified as a Basic Cardiac Life Support instructor. CPR was taught according to American Heart Association standards. Classes were structured to optimize learning and retention of CPR skills and knowledge.[10] To further promote retention, a CPR self-study retention packet for home use was mailed to subjects 3 and 6 months after CPR training.[11] Each packet consisted of the following: (1) a booklet outlining the steps in CPR and the components of properly performed CPR; (2) a poster illustrating the steps of CPR; (3) a paper pillow case with a torso imprinted on it that, when placed on a pillow, allows practice of hand placement for pulse check and cardiac compressions; and (4) guidelines for use of the packet.

Of the 238 subjects who had learned CPR, 172 (72%) were contacted a mean of 21 ± 6 months after receiving CPR training. Twenty-eight percent of the subjects were lost to follow-up because they had moved, had changed telephone numbers, were unavailable during the follow-up period because of vacation or business, or refused to answer the survey. Subjects were 59 ± 11 years old and had a mean of 14 ± 3 years of formal education. The majority were female (85%) and spouses (98%).

A registered nurse contacted subjects by telephone and administered a structured interview to collect the following information: (1) CPR use by family members, (2) patient mortality, (3) attitudes of family members toward CPR training, and (4) CPR practice and retraining patterns and confidence in one's ability to perform adequate CPR. To identify changes in CPR knowledge over time and to explore the potential relationship between knowledge of CPR and confidence in one's abil-

ity to perform effective CPR, we assessed CPR knowledge 2 weeks and 6 months after training. A 24-item, self-administered questionnaire was used (possible scores ranged from 0 to 24). The multiple-choice items were drawn from the national American Heart Association written CPR test.

Results

Four CPR-trained family members used CPR, three successfully and one unsuccessfully. All instances of use were judged by paramedics to be appropriate. Eleven of the 172 (6.4%) cardiac patients whose family member learned CPR died during the follow-up period. Six patients died of cardiac causes, whereas the remaining five died of cancer and other noncardiac causes. In the patients who died of cardiac-related causes, only one death occurred out of the hospital, and CPR was not performed because the CPR-trained family member was not with the victim at the time of his collapse.

The majority of family members reported positive attitudes toward receiving CPR training (see Table 1). The subjects who reported ambivalent feelings toward CPR training worried that they would have to use CPR and would be unable to perform it successfully. Only five subjects reported negative attitudes toward CPR training, largely based on feeling burdened by a sense of responsibility for the survival of their spouse in the case of a cardiac arrest.

The majority said that they would perform CPR if necessary. A small minority would not or were unsure, citing a lack of confidence. The subjects reporting that they would only perform CPR on their family member cited fear of the acquired immunodeficiency syndrome and lawsuits as reasons.

Of the 172 CPR-trained subjects, only 57 (33.1%) subjects reported practicing with the home-use practice packet. Only 14 (8%) subjects received retraining after their initial CPR training. Nonetheless, at the time of the survey, 134 (77.9%) felt that they could still perform adequate CPR.

There was a significant difference in the scores on the questionnaire testing CPR knowledge that was completed at 6 months after CPR instruction; subjects who practiced with the home use practice packet had a mean score of 19.1 ± 2.6, whereas those who did not practice had a mean score of 15.4 ± 2.7 ($P = 0.005$). The 6-month follow-up scores of subjects who practiced were similar to the 2-week follow-up scores of CPR-trained subjects (79% correct vs 80% correct). The subjects who did not practice achieved scores at 6-month follow-up that were similar to those of control subjects who had never been trained in CPR (64% correct vs 62% correct). To assess the relationship between CPR knowledge and subsequent confidence in one's ability to perform CPR, subjects were divided into two groups (i.e., high and low scorers) based on a median split of the CPR test score. Subjects who scored higher on the CPR knowledge test expressed significantly more confidence in their ability to perform adequate CPR ($\chi^2 = 7.08$, degrees of freedom = 2, $P = 0.03$).

Eighty-seven of the interviewed subjects had not learned CPR as part of the initial study. When queried on telephone follow-up, 16 (18.4%) initially untrained family members subsequently learned CPR in a community CPR training class. The 71 family members who did not learn CPR were asked their reasons for not pursuing CPR training. Five did not learn CPR because their spouse died shortly after the study ended. The remaining 66 untrained subjects described a number of barriers to learning CPR, and these are presented in Table 2. The most common reasons for not pursuing CPR training were lack of time, poor health status (of the family member, not the patient), and inattention.

TABLE 1—Attitudes of Family Members of Cardiac Patients 21 Months After Cardiopulmonary Resuscitation (CPR) Training (n = 172)

	No.	%
Feelings about learning CPR		
Very positive	91	52.9
Positive	62	36.0
Ambivalent	7	4.1
Negative	3	1.7
Very negative	2	1.2
No response	7	4.1
Sense of responsibility conferred by learning CPR		
Too much	14	8.1
Right amount	124	72.1
None or very little	34	19.8
Would subject use CPR if needed?		
Yes	141	81.9
No	8	4.7
Maybe	14	8.1
Only on family member	7	4.1
No response	2	1.2

TABLE 2—Reasons Given by Family Members Who Chose Not to Learn CPR (n = 66)

Reasons Cited	No.	%
Lack of time	27	42.9
Did not occur to subject to learn	13	20.6
Medical problems	9	14.3
Inconvenient or too costly	5	7.9
Lack of information about class	3	4.8
Fearful about responsibility	2	3.2
Doctor or nurse did not recommend it	2	3.2
Fear of the acquired immunodeficiency syndrome	1	1.6
Confident in emergency medical system	1	1.6

Note. Not all family members offered a reason, and several offered more than one. Percentages are based on the number of responses given (n = 63).

Discussion

It is important that the family members of those individuals at high risk for sudden death be trained in CPR. Although the average sudden-death incidence is approximately 5% annually in most cardiac populations (e.g., after uncomplicated myocardial infarction),[12] it can reach as high as 50% in patients with advanced congestive heart failure.[13] Unfortunately, families of cardiac patients appear to be the least likely to be trained in CPR.[4,14] Our results also suggest that family members do not seek training on their own. Subjects provided a variety of reasons for not learning CPR, and almost none of these explanations involved fear of too much responsibility or fear of not being able to learn CPR. Although poor health status of the family member proved to be a significant impediment to learning CPR for some, the majority of family members simply chose not to attend to the need for training. This inattention can be addressed by a physician's referral and community education programs, particularly those that target senior citizens and family members of cardiac patients for CPR training.

Many physicians believe in the importance and appropriateness of CPR training for family members of patients with coronary disease, yet fewer than 50% (and in one study[7] fewer than 10%) of physicians recommend CPR training to the family members of their cardiac patients.[5,6] In hypothesizing why physicians' behaviors are at odds with their be-

liefs, Goldberg[9] postulated that physicians believe their patients' families will not understand the importance of CPR training or fear that family members will be unduly frightened if the physician discusses the possibility of sudden death and recommends CPR training. The reluctance of health professionals to recommend CPR training based on such fears, however, may be inappropriate. Once trained in resuscitation techniques, families in the current study did understand the importance of learning CPR and held positive attitudes about having learned it. CPR-trained family members of cardiac patients did not feel that CPR training conferred excessive responsibility. The majority of subjects expressed willingness to use CPR when needed. Those CPR-trained family members who had been called on to use their CPR skills were able to use them successfully and appropriately.

The majority of subjects in the current study did not practice CPR after receiving training and very few retrained in a community CPR course, yet most felt they could perform adequate CPR if called on to do so. Subjects who practiced achieved a score of 80% on a CPR knowledge test at 6 months, whereas subjects who did not practice had a mean score of 64%. Although it is not known how these differences in knowledge might translate to differences in CPR skills in an emergency, the scores of the group who did not practice were similar to those of family members who never learned CPR. These findings indicate that CPR knowledge deteriorates in families, just as it does in health care professionals, and that families do not realize the importance of practice or retraining for maintenance of learned skills and do not appreciate the deterioration of CPR skills that occurs without appropriate reinforcement.[11,15] Clearly, families need to understand the importance of practice and retraining.

In summary, health care professionals should recommend CPR training to the majority of family members of patients at risk for sudden cardiac death. Once trained, families need to be encouraged to retrain annually. The majority of family members do not feel overburdened by training and fears in this regard are unjustified. □

Educating Patients with Limited Literacy Skills: The Effectiveness of Printed and Videotaped Materials about Colon Cancer

Cathy D. Meade, PhD, RN, W. Paul McKinney, MD, and Gary P. Barnas, MD

ABSTRACT

We investigated whether printed or videotaped information is more effective in enhancing colon cancer knowledge. Subjects (n = 1100) were randomized into three groups: to receive a booklet, view a videotape, or receive no intervention. Subjects receiving the intervention showed increased knowledge compared with control subjects (booklet = 23% and videotape = 26% vs no intervention = 3%). Findings suggest that personalized educational materials are effective in enhancing colon cancer knowledge. (*Am J Public Health.* 1994;84:119–121)

Introduction

Colon cancer, the second most common malignancy among men and women in the United States, results in over 61 000 deaths each year.[1] Efforts to reduce colon cancer mortality and morbidity focus primarily on early detection and treatment, given the high survival rate in early stages of the disease.[2–5] Printed materials are commonly used to communicate screening guidelines and detection practices, yet they are often produced at reading levels above that of the intended reader.[6–9] For those with low reading skills, videotapes may offer a significant advantage over printed materials because of their visual appeal. Videotaped instruction has been demonstrated to be as effective as other instructional methods and often more effective than printed materials alone.[10–12] Though the efficacy of written and videotaped methods has been widely reported,[10,13–15] we believe this is the first study to compare the effect of printed vs videotaped colon cancer information on enhancing knowledge among individuals with limited reading skills.

Methods and Measures

Pilot data from 85 clinic patients revealed that most did not recognize that colon cancer was common, were not familiar with American Cancer Society screening guidelines, and felt that a colostomy was necessary when colon cancer was detected. A disparity between stated median educational level (grade 10) and the median reading level as estimated by the Wide-Range Achievement Test II[16] (grade 6) confirmed earlier results.[17]

Instruments

The instruments were produced by the investigators and were based on current cancer literature, a panel of experts, and our pilot data.

Booklet. Bold advance headers introduced the reader to the five sections of the 8½ × 17-inch trifold booklet: facts about colon cancer, facts about the colon and rectum, signs and symptoms of colon cancer, early detection of colon cancer, and a summary. *Colon Cancer: Early Detection Can Save Your Life* was printed in 12-point type with 14-point headers and written at a grade 5–6 reading level.[18,19]

Videotape. Content of the videotape mirrored that of the booklet. Similar headings were placed in the videotape to create visual cues for the viewer. The videotape was filmed in our clinic and showed familiar surroundings. The incorporation of modeling[11] was evidenced by showing patients participating in desired screening behaviors. The videotape was 7½ minutes in length, which approximated the time required to read the booklet.

Pretest/posttest. To evaluate colon cancer knowledge and recall, 24 questions written at grade 5–6 reading level were developed by the investigators and evaluated by a panel of experts. Cronbach's internal consistency alpha coefficient was calculated (r = .63). Questions were systematically divided into two, 12-question tests based on question content, reliability measures, item difficulty, and logical pairing of questions. Each test was comprised of eight true or false and four multiple-choice questions.

Study Population and Data Collection

Subjects (n = 1100) were selected from the Primary Care Clinic at the Milwaukee County Medical Complex, a ma-

TABLE 1—Summary of Scores, by Group

	Intervention Groups		
	Control (n = 356)	Experimental-Booklet (n = 370)	Experimental-Videotape (n = 374)
Pretest (range: 1, 12)			
Mean	7.5	7.5	7.4
95% confidence interval	7.3, 7.7	7.3, 7.7	7.2, 7.6
Posttest (range: 0, 12)			
Mean	7.7	9.2	9.3
95% confidence interval	7.5, 7.9	9.0, 9.4	9.1, 9.5
Score difference (range: −5, 10)			
Mean	0.2	1.7	1.9
95% confidence interval	0.0, 0.4	1.4, 1.9	1.7, 2.2
Score improvement (post-pre)/(pre)	3%	23%	26%

TABLE 2—Mean Scores, by Medium (Booklet or Video) and Reading Skill Level

Medium	Reading Skill[a]	No.	Scores (mean ± SD)		Mean Score Difference	95% Confidence Interval
			Pretest	Posttest		
Booklet	Low	184	7.05 ± 1.72	8.6 ± 1.73	1.54	1.23, 1.85
Booklet	High	185	8.05 ± 1.83	9.85 ± 1.60	1.79	1.49, 2.09
Videotape	Low	216	6.89 ± 1.99	8.68 ± 1.79	1.79	1.45, 2.11
Videotape	High	158	8.01 ± 1.60	10.15 ± 1.68	2.13	1.82, 2.44

[a]Low = Wide-Range Achievement Test II score below grade 7. High = Wide-Range Achievement Test II score at grade 7 or higher.

jor teaching affiliate of the Medical College of Wisconsin. Selection criteria included age of 50 years or older, ability to speak and read English, absence of visual and hearing impairments, ability to give free consent, and eligibility for at least one colon cancer screening measure within the recommended interval. Subjects were allocated randomly by the permuted block method into one of three groups: control, booklet, or videotape. All subjects were first given the pretest. Control group subjects received no educational intervention. Other subjects either were asked to read the booklet or view the videotape. All subjects were given the posttest and the Wide-Range Achievement Test II[17] and were questioned about their demographic background. SPSS-X computer programs were used to perform the analyses.

Results

There were no significant differences in age (mean = 60.6 years), race (54% Black, 44% White), sex (72% female), and Wide-Range Achievement Test II Scores among the groups. The median level of reported education was grade 11, and the median reading level estimated by the Wide-Range Achievement Test II was grade 7, a difference of 4 grades. With a one-way analysis of variance, no significant differences were found in the pretest scores among the groups (Table 1). Tukey's Honestly Significant Difference analysis revealed that the difference in posttest minus pretest score between each intervention group and the control group was large enough to be significant at the .05 level of confidence. No statistically significant difference was noted between the booklet and videotape groups.

Subjects in both experimental groups were then divided into four groups according to their Wide-Range Achievement Test II scores (Table 2). Those with grade 7 or higher scores were considered to have high reading skills, whereas those with lower than grade 7 scores were considered to have low reading skills. This definition was based on their expected reading ability within 2 years of the reading level of the booklet. No statistically significant differences in score improvements were found among the four subgroups according to analysis of variance.

Discussion

Both printed and videotaped materials enhanced colon cancer knowledge among patients with limited literacy skills. One possible explanation for this finding is that the interventions were tailored to our target group, with special attention given to developing content relevant to their learning needs, designing the instruments to reflect ethnic diversity, organizing content in a clear manner, using the active voice, writing or narrating in a conversational style, using short words and sentences, incorporating headers and cues, summarizing points, and pretesting the tools.[20–26] The effectiveness of both educational media in enhancing patient knowledge also may have been influenced by consideration of our patients' attitudes towards colon cancer and associated procedures,[27] as well as by the use of the pretest. Our findings support the hypothesis that printed materials written at low reading levels (grade 5–6) can be effective substitutes in clinics without access to expensive audiovisual equipment.[28–30] We recommend that formative and summative evaluations of educational materials be done to ensure that they are acceptable, appropriate, and comprehensible to the target group.[6,20,24]

The inference from our data that both interventions enhanced patients' knowledge about colon cancer should be viewed with caution because only short-term knowledge recall was evaluated. Future studies will be required to determine how long this knowledge is retained and its effect on attitudinal and behavioral outcomes. □

Call for Nominations for 1994 Public Health Nutrition Awards

The Food and Nutrition Section of the American Public Health Association would like to honor individuals who have made outstanding contributions to nutrition within public health. Nominations are being solicited for the Mary C. Egan Award, the Catherine Cowell Award, and the Excellence in Dietary Guidance Award. The Catherine Cowell Award is presented to an individual who is innovative and who has a keen vision in developing programs in public health nutrition. The Mary C. Egan Award recognizes professional contribution to and special service in public health nutrition.

Nominations must be received by *May 1, 1994.* For more information contact Yvonne Bronner, PhD, RD, Johns Hopkins University, School of Hygiene and Public Health, Department of Maternal and Child Health, 624 N Broadway, Room 245, Baltimore, MD 21205; tel (410) 955-3804.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Factors Influencing the Duration of Work-Related Disability: A Population-Based Study of Washington State Workers' Compensation

ABSTRACT

Objectives. The purpose of this study was to examine factors predictive of duration of work-related disability.

Methods. Multivariate survival analysis techniques were used to conduct a population-based, retrospective cohort study on a random sample of 28 473 workers' compensation claims from Washington State filed for injuries occurring in 1987 to 1989. The principal outcome measure was length of time for which compensation for lost wages was paid, used as a surrogate for duration of temporary total disability.

Results. The findings suggest that, even after adjusting for severity of injury, older age, female gender, and a diagnosis of carpal tunnel syndrome or back/neck sprain significantly predict longer duration of disability. Other predictors that were stable and significant, but involved lower magnitudes of effect included divorced marital status, firm size of fewer than 50 employees, higher county unemployment rates, and construction and agricultural work.

Conclusions. Greater disability prevention efforts targeting these higher risk subgroups could have significant economic and public health effects. The greatest impact may be on claimants who remain disabled at 6 months after an injury that did not require hospitalization. (*Am J Public Health.* 1994;84:190–196)

Allen Cheadle, PhD, Gary Franklin, MD, MPH, Carl Wolfhagen, MPA, James Savarino, PhD, P. Y. Liu, PhD, Charles Salley, MS, and Marcia Weaver, PhD

Introduction

Disability associated with work-related injuries is an increasingly serious problem in workers' compensation. Among work-related injuries, the small fraction of disabilities that are of long duration account for a large fraction of workers' compensation costs.[1] More important, if an injured worker has not regained satisfactory work status 2 years after the injury, his or her chances of doing so thereafter are very low.[2] Given the high costs to society of lost productivity and the high human costs of disability to an injured worker, long-duration work-related disability is a serious public health concern.

Although many studies have investigated factors that predict disability after work-related injuries,[3–17] most have been limited to specific types of injury; have used relatively small, non-population-based samples; or have not adjusted for severity of injury. This paper reports on analyses conducted on a random sample of all workers' compensation claims from Washington State filed for injuries occurring in 1987 to 1989. Because Washington is one of six states where employers are required to obtain workers' compensation insurance exclusively through a state fund (or to self-insure), the sample is broadly representative of work-related injuries occurring in the state for that time period. Survival analysis techniques were used to predict duration of disability as a function of injury nature and severity and a variety of worker, firm, and industry characteristics.

Methods

Sampling Frame and Study Design

All workers' compensation claims filed between January 1, 1987, and December 31, 1989, were identified through the extensive claims and medical bill payment databases of the Washington State Department of Labor and Industries. For the purposes of this study, only employees with claims involving at least 4 days of time lost from work (compensable claims) were considered to be at risk for long-term disability (Figure 1). Exclusions from the baseline population were as follows: (1) claims involving 3 or fewer days lost from work as a result of occupational injury or illness (noncompensable claims) and (2) claims from self-insured employers (approximately 350 employers, representing one third of covered workers), whose reporting requirements are inadequate for research purposes.

A random sample of 10 000 compensable claims was drawn in each of the 3 years. Claims with missing information for one or more independent variables (n = 1527; 5.1%) were deleted from the sample, leaving a final incidence cohort of 28 473 claims. A total of 592 claims (2.0%) lacked the worker's monthly wage; an-

other 935 (3.1%) had missing data on other covariates. Duration of disability and most of the demographic variables were not significantly different between included and excluded claims; when there were significant differences, the magnitudes were small. This 26% sample of the total compensable claim population represents the work-related disability experience of two thirds of the nonfederally covered workers in Washington State (approximately 900 000 full-time equivalent workers).

The study involved a population-based, retrospective cohort design[18] (Figure 1), with duration of disability serving as the principal outcome measure. Time-loss data were extracted in June 1991; the mean duration of follow-up for the cohort was 35.4 months. All known or suspected predictors of disability duration (Table 1) were obtained from (1) computerized claim data collected from the initial accident report (gender, age, marital status, dependents, benefit rate [from baseline wage], type of injury, injury date, county of injury, type of firm ownership [public or private], and Standard Industrial Classification code); (2) medical bill payment data (the injury severity marker was hospitalization within 28 days of injury); (3) state unemployment surveys (county unemployment rate); (4) work hours reported by the employer, measured in the number of full-time equivalent workers employed (firm size); and (5) computerized codes relevant to premium rating (experience vs retrospective rating).

The US Department of Labor Z16.2 codes developed by the American National Standards Institute were used in categorizing the nature of injuries. These codes have wide use in workers' compensation systems. Although carpal tunnel injuries involved a body part code of upper extremity, wrist, or hand and were classified as nervous system condition/disease or bursitis, the Department of Labor and Industries specifically coded for this condition during the time period under study.

The state workers' compensation fund has two ratings that adjust the premium costs paid by employers to reflect their accident costs: experience rating and retrospective rating. Time-loss and medical costs are experience rated for all employers based on a 3-year average of past costs. Retrospective rating is an optional incentive system available to state fund employers. Employers with a rating better than the average of those for their job classifications and better than their own past ratings receive a refund of the difference; those whose ratings decline pay the difference to the state. Firms in the retrospective rating program have disability prevention incentives similar to those of the self-insured firms excluded from our sample of claims.

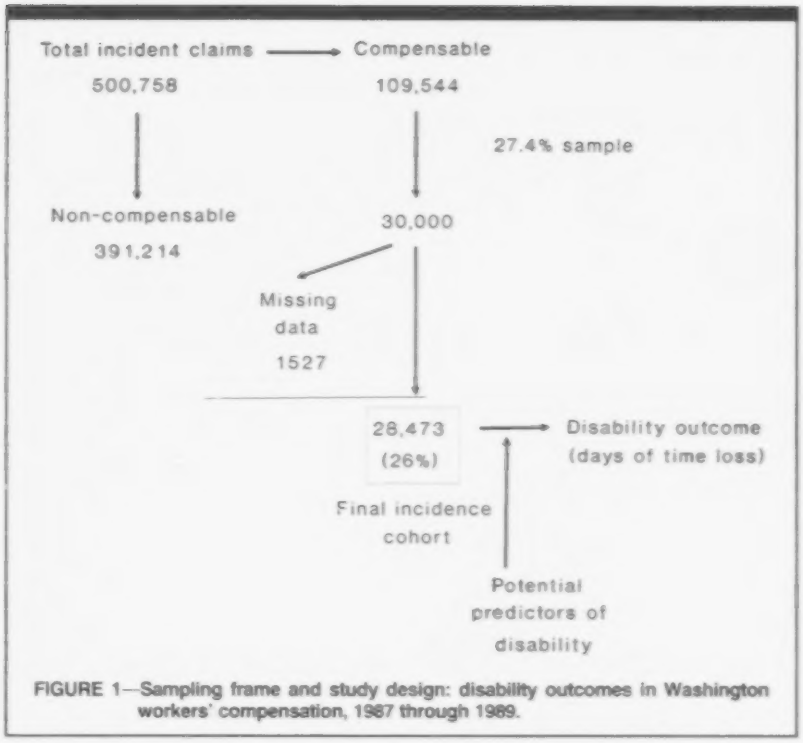

FIGURE 1—Sampling frame and study design: disability outcomes in Washington workers' compensation, 1987 through 1989.

The last set of variables shown in Table 1 was included to capture the effect of the benefit structure on duration of disability. The basic benefit rate in Washington is 60% of the monthly wage at the time of injury. The rate increases on the basis of marital status (workers with a spouse receive an additional 5% benefit) and number of dependents (2% per dependent, up to a maximum of 10%). The maximum benefit rate, regardless of monthly wage, is 75% of the state average weekly wage prior to July 1, 1988, and 100% of the average weekly wage after July 1, 1988. The minimum monthly benefit of roughly $200 also varies on the basis of marital status and number of dependents.

Since the benefit rate for most workers in our sample was determined by their marital status and number of dependents, we could not separate out the independent effect of the benefit rate on return to work. However, for workers with a monthly wage above that yielding the maximum benefit amount (maximum benefit/.6), the benefit rate did not depend on either marital status or number of dependents. In preliminary analyses, we included a dummy variable equal to 1 when the wage was above this maximum amount, as well as a term for the interaction between this dummy variable and the benefit rate. The coefficient for this interaction variable, approximating the "pure" effect of the benefit rate for a select sample of high-income workers, was not statistically significant. Therefore, we used only the simpler specification shown in Table 1 to control for the effect of workers' compensation benefits on duration of disability.

In another preliminary analysis, we linked the 1980 census occupational codes recorded on the claim form to a file containing a variety of job characteristics, including educational requirements, prestige, and income.[19-21] These indirect measures of socioeconomic status were generally insignificant or inconsistent predictors of disability duration; consequently, only the benefit rate variables were included in the final analysis.

All of the variables included in the model are categorical. For continuous variables (age, benefit rate, firm size), the analysis was also performed with a continuous specification (including a quadratic term). In all cases, the results were very similar regardless of specification, and categorical results are reported here for ease of interpretation.

The claim rather than the worker was the unit of analysis, and a small percentage of workers in our sample (2.8%) had mul-

tiple claims during the 3-year study period. Theoretically, all of these multiple claims, if given a separate identifier, should have involved new injuries and therefore could be regarded as independent events. However, individual characteristics probably influenced the duration of disability for all injuries for a particular worker, however dissimilar the injuries. To examine the impact of these claims on the results, one claim was selected at random from all workers with more than one claim, and the analyses reported below were rerun. The results were virtually identical to those reported here, and it was concluded that any potential nonindependence effect due to multiple claims was relatively minor.

Statistical Analysis

Survival analysis techniques were used to model duration of disability as a function of the independent variables. Cox regression models,[22,23] which make relatively few assumptions about the shape of survival curves, were used in these analyses. The principal assumption of the Cox model is that the relative "hazard" (in this case, the likelihood of returning to work at a given point in time) is constant over time for each categorical variable. For example, if men are twice as likely as women to return to work at 30 days, they should also be twice as likely to do so at 90 days, 180 days, and so forth. To verify that the proportional hazard assumption underlying the Cox model was met, we plotted the relative hazards over time for each categorical variable. All of the variables included met the proportional hazard assumption.

Because of the large number of claims in our sample, it was common for the coefficients to be highly significant but small in magnitude. Therefore, we imposed the additional criterion of "stability" in determining which results to give emphasis. In particular, we ran the survival analysis for each calendar year sample separately and compared the resulting coefficients across years. Results were classified as stable and significant if, in each of the 3 years, they (1) were statistically significant and (2) had the same sign and roughly the same magnitude (within a band of 50% of the average coefficient value).

Results

Figure 2 shows a survival curve (Kaplan-Meier) of the percentage of claims in the sample by duration of disability, unadjusted for covariates. The figure demonstrates that most disability du-

rations were short term; by 1 month, more than half of the employees had returned to work. Table 1 provides descriptive statistics for the variables used in the multivariate analysis. Of those filing claims, three quarters were men, only 17% were older than 45 years of age, and half were married at the time of the injury. The largest single category of injury was back sprains (34%), followed by other sprains and strains (20%). Six percent of the claims involved a hospitalization in the first 28 days after the date of injury. Slightly more than one third of the claims were filed in King County (Seattle metropolitan area), and 57% were filed by workers in small firms (fewer than 50 employees).

The mean disability durations for each category shown in Table 1 are included for purposes of illustration only. Censored claims were included in the calculations, and, since categories with claims of longer duration will also have more censored claims, the true differences in duration across categories (e.g., across age groups) are probably understated. Given this caveat, the unadjusted differences in duration across categories ranged from a few days to nearly 5 months in the case of injuries with and without hospitalization.

Table 2 presents results from a Cox proportional hazards regression that included all of the independent variables in Table 1 for the 1987 to 1989 combined sample. For each variable, the coefficient and standard error are shown, as well as the relative hazard (exponent of the coefficient) and its confidence interval. For example, women were only 84% as likely as men to return to work at any given point in time. As noted above, we distinguished between effects found to be stable and significant over the 3-year period from other effects that were either insignificant in some years or had large changes in sign and/or magnitude. The largest effects involved injuries requiring hospitalization (relative hazard = 0.48), carpal tunnel injuries (relative hazard = 0.55), and older workers (relative hazard = 0.67). The coefficients on the other stable and significant variables, while smaller in magnitude, indicate that workers with a longer duration of disability were more likely (1) to be women, older, and divorced; (2) to have dependents; and (3) to work in smaller firms. In addition, workers in counties with high unemployment rates and those in general construction were more likely to have claims of longer duration. Workers in wholesale trades were the least likely to have such claims.

TABLE 2—Survival Analysis: Cox Proportional Hazards Model, 1987–1989 Combined Sample

	Relative Hazard[a]	95% CI[b]

Unemployment rate, %		
<5	1.00	
5–7	0.99	0.95, 1.04
>7	0.88	0.82, 0.95

Some other results were noteworthy, even though they did not meet our criteria of stable and significant. Workers at firms participating in the retrospective rating program over the entire period had a significantly greater chance of returning to work (relative hazard = 1.14), although the effect of participation at the time of injury was insignificant. None of the benefit-rate variables were significant at $P = .01$, even in the combined sample of claims.

Figures 3 and 4 present results from the Cox regressions in an alternative, perhaps easier to interpret, form. The survival curves show the estimated disability survival probabilities (in percentage points), based on the model in Table 2, evaluated at durations of 1 to 8 months. The lower curve in each figure is the "reference" case, with values of 0 for all of the independent variables. In particular, the reference case model is male, under 30 years old, and unmarried; has no dependents; and has an injury other than sprains, fractures, and carpal tunnel syndrome that did not require hospitalization in the first 28 days after occurrence. The other curves show the effect of changing *only* the indicated variable. For example, the effect of being in the 30- to 44-year-old age range raises the estimated proportion of claims involving 6 months or more of disability from roughly 5% to 10%. The cumulative effect of changing several cat-

egories at once (not shown) can be quite large; for example, a married man more than 45 years old with dependents and an injury requiring hospitalization raises the proportion of claims involving at least 6 months of disability from 6% to 45.3%.

Discussion

Using a large random sample of all incident disability claims from the Washington State workers' compensation system, this investigation has shown that, after adjusting for initial hospitalization, factors that predicted longer duration of disability included older age, female gender, and a diagnosis of carpal tunnel syndrome or back/neck sprain. Other stable and significant predictors with lower magnitudes of effect included divorced marital status, firm size of fewer than 50 employees, higher county unemployment rates, and construction and agricultural work. Workers from wholesale trades were at decreased risk for longer term disability. Wage replacement had no significant effect on duration of disability.

This population-based study suggests that 17.5% of all initial disability claims involved at least 6 months of lost time, 12% involved 1 year of lost time, and 7.4% involved at least 2 years of lost time (see Figure 1). Only 12.1% of those claims in which at least 6 months of lost time accumulated involved injuries requiring hospitalization within 1 month of occurrence.

Before comparing our results with other studies, we should note that we defined disability as the loss of capacity to meet occupational demands as opposed to loss of personal or social functioning. The studies cited below share this focus on work-related impairment.

Many studies have focused on a specific type of injury and therefore have not been able to isolate the impact of injury type on duration. Studies including injury type have also found sprains and fractures to be associated with longer duration.[8] The most interesting injury-type finding here is the long duration of carpal tunnel claims, a result that was consistent across years and not apparently due to outliers. The carpal tunnel results should be viewed as preliminary given the small number of claims in this category (2%) and the relative crudeness of the method for identifying such claims (use of Z16.2 codes). Franklin et al.[24] found some misclassification even with more detailed medical information about the injury and more stringent criteria for classifying claims as carpal tunnel injuries.

Injury severity is another variable that has not been widely used in other studies. Our ability to characterize the nature and severity of the injury was limited by the quality of the medical billing database. We chose 1 month as the cutoff interval as a compromise between (1) ensuring that there was adequate time for the appropriate injury treatment to be chosen and (2) ensuring that the hospitalization shown in the billing record was primarily due to the particular work-related injury. Other studies that have used hospitalization as a proxy for severity[10] have also found it to be correlated with disabilities of longer duration. In our data, a hospitalization within the first 28 days was the strongest and most consistent correlate of longer term disability.

A number of worker and family characteristics, of which older age is the most important and consistent, have been found to influence duration of disability.[2,8–11] The age effect is due both to the reduced ability of older workers to recover from injuries and to the reduced likelihood of finding employment once they have recovered. Gender has not figured prominently in previous studies, partly because a much

smaller proportion of women file workers' compensation claims. In our analysis, women had disabilities of longer duration, as has been found in other studies in which gender has been included as a variable.[11] Divorced workers have also been found in other studies to have longer term disabilities.[3,4]

Several personal characteristics not available on the Washington database have been identified as correlates of disability duration, particularly indicators of socioeconomic status. Higher socioeconomic status is expected to be associated with fewer claims and shorter duration.[3,4,12] Manual labor occupations have also been associated with disabilities of longer duration when other factors have been controlled.[10,11] A number of studies have found that higher workers' compensation benefits result in longer duration.[5,7,9,10] We did not find an association between the wage replacement rate and duration; however, as noted above, the replacement rate was confounded with marital status and number of dependents. Also, because of the confounding problem, we did not pursue other, perhaps more accurate measures of the income replacement rate such as after-tax income.

Three British studies and one American study[9–11,14] have also reported finding a longer duration (or higher incidence) of disabilities in areas with high unemployment rates. This indicates that duration of disability may be sensitive to the prospects for employment in the immediate area. This result should be viewed with caution given the difficulties involved in estimating the effect of aggregate variables on individual-level behavior.[25]

Industry results are scarce in the literature,[6,9] and few consistent patterns have emerged. As noted above, the industry effects in our analysis were also not significant or consistent across years. In the combined sample, workers in construction and agriculture tended to have disabilities of longer duration, while disabilities in trade and services were of shorter duration.

Size was the single firm characteristic that was a stable and significant predictor of duration, with larger firms having shorter durations of disability. This result is consistent with other studies.[5,17] Drury[17] has suggested a number of reasons for smaller firms having more disability claims and longer durations of disability: the ability of larger firms to employ specialists in disability management, exemption of smaller firms from laws requiring disability benefits, and high turnover and less access to information about disability prevention in smaller firms. Another factor providing large firms more incentive to shorten claims is their greater experience ratings in standard premium calculations.[26] This predicted effect of experience rating is consistent with our finding that participants in the retrospective rating program (in which the experience rating is more complete) had claims of shorter duration. Finally, larger firms may have greater flexibility in allowing workers to return to modified jobs.

There are some qualifications and limitations to our results that should be noted. First, the data were from an administrative database and therefore subject to a certain amount of entry errors, miscoding, and misclassification.[24,27] Much of the information used was from the claim form filled out by the physician and coded by the state at the time of injury. Those fields required for billing and claims administration (e.g., marital status, company identifier, hospitalization records) are closely monitored; fields not directly related to billing the state and the firm may be subject to greater error (e.g., injury type). In general, the effect of coding and data-entry errors will be to attenuate the relationships examined in the survival analysis.

The results are obviously specific to Washington State, and caution should be exercised in extrapolating them to other states. Washington does have a relatively diverse set of industries, including resource-based (logging, agriculture), heavy and light manufacturing, and trade and services industries. However, a number of the largest employers—350 representing one third of covered workers—were self-insured and therefore excluded from the study. Firm size and the retrospective rating program were included in the analysis, so some of the effects of size and presence of disability prevention incentives similar to being self-insured were at least partially controlled. Other factors specific to Washington include the claims-handling procedure and system of vocational rehabilitation. A substantial revision of claims handling in early 1989 was intended to reduce the number of long-duration claims, although an effect of this change on disability duration was not found in our sample (Table 2).

A final limitation is that these independent variables measured worker, firm, and industry characteristics only at the time of injury. Other factors related to medical management and vocational rehabilitation were highly correlated with duration of disability; thus, their effects could not be estimated independently within our study design.

This study is subject to a number of limitations; however, its strength was that it (1) was population based, (2) allowed for a mean follow-up of nearly 3 years, and (3) adjusted for hospitalization within 28 days of injury (used as a proxy for injury severity). The principal findings suggest that older workers, women, and patients with carpal tunnel syndrome or low-back/neck sprains are all at a disadvantage in regard to the risk for longer term disability, even after adjustment for hospitalization. Greater disability prevention efforts targeted at these subgroups could have significant economic and public health effects. □

Association for Worksite Health Promotion Sponsors April Conference

Health promotion and disease prevention are pivotal to successful health care reform both nationally and at every local level. A unique conference, "Health Promotion and Health Care Reform: Linking Values and Building Partnerships in the '90s," offers business and health professionals new strategies, modes, and insights on implementing effective worksite and community health promotion programs. The conference will be held April 17 through 19, 1994, at the San Francisco Airport Marriott Hotel, 1800 Bayshore Hwy, Burlingame, Calif.

Featured speakers will include Michael McGinnis, MD, deputy assistant secretary of health, US Office of Disease Prevention and Health Promotion; Ken Pelletier, MD, Stanford Center for Research in Disease Prevention; Susan Seidler, Washington Business Group on Health; Brick Lancaster, MPH, Centers for Disease Control and Prevention; Helen Schauffler, PhD, MSPH, UC Berkeley School of Public Health; and Carson Beadle, The Health Project/William M. Cercer, Inc.

Sponsored by the Association for Worksite Health Promotion (Region 7), an international nonprofit professional organization, the conference is designed for leaders in human resources, benefits, health promotion, and health insurance, as well as occupational health nurses, physicians, and other clinical practitioners. Cosponsors include Lifeguard, Inc., Parke-Davis, Marion Merrell Dow, Merck, Lederle, Bay Sport, Xerox, Longs Drug Stores, Health Dimensions, and Richard P. Carr Physical Therapy.

For registration and conference information, please call (415) 985-2698.

Circumcision and Sexually Transmitted Diseases

Linda S. Cook, MS, Laura A. Koutsky, PhD, and King K. Holmes, MD, PhD

ABSTRACT

Objectives. New evidence linking lack of circumcision with sexually transmitted human immunodeficiency virus revives concerns about circumcision and other sexually transmitted diseases. This study was undertaken to assess the relationship between circumcision and syphilis, gonorrhea, chlamydial infection, genital herpes, nongonococcal urethritis, and exophytic genital warts.

Methods. A cross-sectional study of 2776 heterosexual men attending a sexually transmitted disease clinic in 1988 was used to investigate the relationship between circumcision and sexually transmitted diseases. Subjects with specific sexually transmitted diseases and those without such diseases were compared after adjustment for age, race, zip code of residence, other sexually transmitted diseases, and number of sexual partners.

Results. A positive relationship was observed between uncircumcised status and both syphilis and gonorrhea. A negative relationship was found between warts and lack of circumcision. No apparent relationship was noted between uncircumcised status and genital herpes, chlamydial infection, or nongonococcal urethritis.

Conclusions. Uncircumcised men were more likely than circumcised men to have syphilis and gonorrhea and were less likely to have visible warts. (*Am J Public Health.* 1994;84:197–201)

Introduction

The possible role of male circumcision in the acquisition of sexually transmitted diseases has taken on new significance with recent evidence that human immunodeficiency virus (HIV) infection in men is associated with uncircumcised status.[1–3] Sexually transmitted diseases previously linked with uncircumcised status include chancroid, syphilis, gonorrhea, and genital herpes infection[1,4–7]; however, most of the reported associations between these diseases and uncircumcised status have not been adequately adjusted for potentially confounding factors. The present cross-sectional study was undertaken to examine the relationship between circumcision status and genital infection by *Treponema pallidum*, *Nisseria gonnorhoeae*, and *Chlamydia trachomatis*, in addition to clinical evidence of nongonococcal urethritis, genital herpes, and exophytic genital warts, with adjustment for potentially confounding factors.

Methods

Study Population

The study population included men attending the Seattle–King County Department of Public Health Sexually Transmitted Disease Clinic at Harborview Medical Center between January and December 1988. The clinic, which provides comprehensive services related to sexually transmitted diseases such as diagnosis, treatment, education, and risk reduction counseling, served 80 to 120 patients per day in 1988. The exact number of unique men seen in the clinic in 1988 is unknown; the Department of Public Health tallies new problem visits, to which an individual can contribute multiple times. Among all male visits to the clinic in 1988, 8034 new problem visits were recorded.

Study subjects were identified in 1990 through patient medical charts that had been archived according to the year of visit. Charts are placed into the archives after approximately 1 year if the patient has not returned to the clinic in the interim. Charts of men who returned to the clinic in 1989 were not included in the study. According to statistics compiled by the clinic, the study population closely matched that of all men seen for a new problem in 1988 in regard to cases of syphilis (0.7% vs 0.8%), gonorrhea (8.1% vs 10.0%), warts (14.5% vs 14.2%), chlamydial infection (6.8% vs 6.9%), nongonococcal urethritis (29.0% vs 25.4%), and genital herpes (4.7% vs 5.0%). Thus, the study population was considered a good representative sample. Of the 4137 subjects identified, 897 did not meet the study inclusion criteria (380 who presented for HIV screening only and did not have a genital examination, 306 who were homosexual or bisexual, and 211 who did not reside in King County). Of the 3240 eligible study subjects, 464 did not have circumcision status recorded and were excluded from the analysis. The resulting study population consisted of 2776 heterosexual men.

All data used in this study were abstracted in 1990 from standardized clinic records of men who attended the clinic in

1988. These records included information concerning demographic characteristics of the patient, reason(s) for visit, symptoms, sexual history (new sexual partner in the last month, number of sexual partners in the last month, and days since last sexual exposure), prior sexually transmitted disease history, and results of all physical and laboratory examinations.

All consenting patients seen for a new problem underwent genital examination and had urethral swabs taken for a Gram-stained smear and for cultures for *N. gonorrhoeae* and *C. trachomatis*. Blood for serologic testing of syphilis (reagin antibody) was obtained from all consenting patients, and dark-field examination was performed on suspected syphilitic lesions.

Diagnoses of warts and genital herpes were presumptively based on the clinical appearance of lesions; cultures for herpes simplex virus were obtained when considered necessary by the clinician. Current syphilis was determined by a positive dark-field test from a suspicious lesion or by a positive rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) titer (titer above 1:2) with confirmatory T. pallidum hemagglutination assay (TPHA) serology. This definition included primary, secondary, and some early latent syphilis cases; however, all cases were newly diagnosed.

The diagnosis of nongonococcal urethritis was based on the presence of at least two of the following criteria: subject-reported urethral discharge or dysuria, presence of a purulent urethral discharge on exam, or a urethral Gram-stained smear that showed at least five polymorphonuclear leukocytes per 1000X oil immersion field for at least three fields. The combination of the first two criteria was used only if the *N. gonorrhoeae* culture was negative. A subset of subjects (n = 278) had elevated polymorphonuclear leukocytes on urethral smear; these subjects were given a clinical diagnosis of nongonococcal urethritis and treated for this condition but were not recorded as having an abnormal urethral discharge. Addition of these subjects to those in the more stringently defined category of nongonococcal urethritis did not alter the study results, so they were combined in the final analysis.

For this study, the principal sexually transmitted diseases evaluated were laboratory-confirmed *N. gonorrhoeae, C. trachomatis*, and *T. pallidum* infection and clinical evidence of nongonococcal urethritis, genital warts, or genital herpes. The "other sexually transmitted disease" category comprised subjects with a variety of diagnoses, including pediculosis pubis (n = 81), scabies (n = 33), and molluscum contagiosum (n = 69). The reference group was composed of subjects who were not diagnosed with any of the above sexually transmitted diseases or conditions. Circumcision status was recorded by the clinician as part of the routine examination. Place of residence in King County was categorized by zip code into six Seattle areas and one non-Seattle area, as explained in detail elsewhere.[8]

Statistical Analysis

The initial 1988 clinic visit of each subject was used for analysis. The prevalence of each of the principal study diseases was determined on the basis of circumcision status. In order to allow direct sexually transmitted disease prevalence comparisons between circumcised and uncircumcised men, prevalences were standardized to the combined age and race distribution of the entire study population.

Characteristics of those with sexually transmitted diseases and those in the reference group without such diseases were compared. Odds ratios (ORs) were used as the measure of association to assess the relationship between circumcision status and each disease category. Logistic regression[9,10] was used to calculate adjusted odds ratios and the associated 95% confidence intervals (CIs). Since subjects could have multiple sexually transmitted disease diagnoses, all variables were placed in a single model to allow for the control of multiple diseases. Therefore, adjusted odds ratios reflect an association between a particular sexually transmitted disease and circumcision status that is not influenced by the presence of other sexually transmitted diseases. All analyses were conducted with SAS.

Results

Prevalences of Sexually Transmitted Diseases Under Study

Age- and race-standardized prevalence figures revealed that, in this clinic population, the prevalence of current syphilis was higher in uncircumcised men than in circumcised men (2.5% vs 0.6%; $P < .001$), as was the prevalence of gonorrhea (12.7% vs 8.1%; $P < .01$). Conversely, the prevalence of exophytic warts was higher in circumcised men (17.6% vs 11.0%; $P < .001$). No significant differences between uncircumcised and circumcised men were observed for prevalences of nongonococcal urethritis, (30.2% vs 32.7%), genital herpes (8.8% vs 8.7%), or urethral infection with *C. trachomatis* (7.2% vs 6.4%).

Subject Characteristics Related to Current Diagnosis

The study population, composed of 540 uncircumcised men (19.5%) and 2236 circumcised men (80.5%), is described in Table 1 according to sexually transmitted disease status. In comparison with the reference group, those with gonorrhea, chlamydial infections, and genital warts were younger ($P < .05$); subjects with a diagnosis of current syphilis, gonorrhea, chlamydial infection, or nongonococcal urethritis were more likely to be African American, whereas those with exophytic warts were more likely to be White. Subjects with current diagnoses of gonorrhea, chlamydial infection, and nongonococcal urethritis more often reported a new sexual partner in the previous month and two or more partners in the previous month than those in the reference group. Subjects diagnosed with any of the principal study sexually transmitted diseases were more likely than those with no disease diagnosis to present at the clinic with symptoms and less likely to present for screening.

Association of Uncircumcised Status with Current Disease Diagnosis

Crude and adjusted odds ratios for the association of uncircumcised status with the study diseases are presented in Table 2. Adjusted odds ratios were estimated by fitting a multiple logistic regression model adjusted for age, race, number of sexual partners in the previous month, place of residence, and the other sexually transmitted diseases. No adjustment was made for a new partner in the last month, days since last sexual exposure, marital status, and reason for visit because of their negligible effects on the estimated odds ratios. No adjustment was made for a prior history of sexually transmitted diseases because any influence of circumcision status was assumed to be the same for a prior diagnosis as for the current diagnosis, and adjustment would have controlled for the associations the present study sought to quantify. In the adjusted analysis, an elevated odds ratio was noted for the association of uncircumcised status with current syphilis (OR = 4.0, 95% CI = 1.9, 8.4) and gonorrhea (OR = 1.6, 95% CI = 1.2, 2.2). A negative association was noted for warts and uncircum-

cised status (OR = 0.7, 95% CI = 0.5, 0.9). Uncircumcised status was not associated with nongonococcal urethritis, genital herpes, or urethral infection with *C. trachomatis*.

Discussion

The results of this study support the hypothesis that circumcision status is related to some, but not all, sexually transmitted diseases. The positive findings associating syphilis and gonococcal infections with uncircumcised status in the present study were similar to those previously reported by the Public Health Department Special Treatment Clinic in Perth, Australia.[6] Age-adjusted results from the Perth study indicated a positive relationship with both syphilis (OR = 5.4, 95% CI = 1.4, 21.1) and gonorrhea (OR = 2.3, 95% CI = 1.5, 3.7). Contrary to results in the present study, the Perth study also found a positive relationship between uncircumcised status and herpes and warts. Discrepancies between the two studies could be due to the present study's finer adjustment for confounding variables and restriction to heterosexual men.

Other studies have also investigated specific relationships between certain sexually transmitted diseases and uncircumcised status. In a study conducted at the Whitechapel Clinic in London, a comparison of men with culture-confirmed herpes and controls revealed a higher proportion of men with herpes being uncircumcised.[5] Interpretation of this finding is limited since the control group consisted of men with a number of other sexually transmitted disease diagnoses that each could have had a specific relationship with circumcision status. A study of active duty army men found that uncircumcised status was protective for nongonococcal urethritis

TABLE 2—Odds Ratios Associating Study Sexually Transmitted Diseases with Uncircumcised Status

Other sexually transmitted diseases	26	154	0.7	0.8	0.5, 1.2

[a]Adjusted for age group (13–19, 20–24, 25–29, 30–34, 35+), race/ethnicity (White, African American, other), number of sexual partners in the last month (0, 1, 2+), place of residence (six Seattle areas and one non-Seattle area defined by zip codes), and the other sexually transmitted diseases.

but not related to gonococcal infection.[11] Although that study adjusted for important confounders, direct comparisons with the present study are difficult since the former included subjects who apparently contributed to the case groups several times. In the final analysis, there were approximately five times more men in both the gonorrhea and nongonococcal urethritis groups than in the control (no sexually transmitted disease) group. In addition, the ratio of nongonococcal urethritis cases to gonorrhea cases was much lower than that typically observed in sexually transmitted disease clinic populations. Finally, a study of Canadian army men reported a higher proportion of uncircumcised active duty men with warts and syphilis compared with the proportion of uncircumcised men among new recruits.[12] Although suggestive, the results could easily be biased as a result of the comparison of two distinctly different groups of men.

It was not possible to evaluate chancroid because it was not found in this study population. It was also not possible to evaluate HIV infection as a result of its very low prevalence (estimated to be 0.6% among heterosexual men seen in the clinic from June 1988 through December 1990). Therefore, no comparisons can be made with the many studies linking uncircumcised status with chancroid, including recent studies from East Africa that have linked uncircumcised status with both chancroid and HIV seroconversion.[1-3]

Mechanisms for differential risks of sexually transmitted diseases based on circumcision status remain undefined. Possible theories include the following: (1) trauma of the intact foreskin during sexual intercourse produces microscopic lesions that increase susceptibility; (2) the environment under the foreskin could extend the survival of infectious agents and thus prolong exposure to viable organisms; (3) the thinner, less cornified epithelium on the glans and preputial sac of an uncircumcised male may provide less of a physical barrier to microbial invasion; and (4) nonspecific balanitis, not uncommon in uncircumcised men, may predispose to certain sexually transmitted diseases.

The finding that circumcision status is associated with some but not all sexually transmitted diseases may be related to the differing pathogenesis of these diseases. For syphilis, entry by *T. pallidum* is thought to occur through microscopic abrasions and not through undamaged, keratinized epithelium.[4] In uncircumcised men, trauma of the foreskin or the thin epidermis of the glans during sexual activity can open a passageway of infection for treponemes. The thicker, cornified epithelium on the glans of a circumcised male may be less susceptible to abrasions and, therefore, to entry by *T. pallidum*. For gonorrhea, the inner lining of the foreskin[13] might create an environment conducive to the survival or growth of *N. gonorrhoeae* and, perhaps, to entry into the urethra and enhanced infectivity.

A limitation of the present study arises from the available information on genital herpes and genital warts. For genital herpes diagnosis was based on the presence of clinical lesions, with or without confirmatory cultures, and subclinical infections could have been undetected. If uncircumcised subjects were more likely to have inapparent infections, this study could have underestimated the true association of uncircumcised status with genital herpes. The finding that genital warts were less likely to be diagnosed in uncircumcised men was of interest. Further information on the anatomic distribution of penile warts is actually the relevant information for assessing the influence of circumcision status on wart lesions and will be addressed in a subsequent paper.

A possible concern is that the study subjects presumably came to the clinic as a result of a problem related to a sexually transmitted disease and that, therefore, an elevated prevalence of one disease would predict a lower prevalence of some other disease. In this cross-sectional population, subjects were not selected on the basis of the presence of symptoms related to, or a diagnosis of, a sexually transmitted disease. Thirty-five percent of the study population did not have a sexually transmitted disease diagnosis. Furthermore, a subject could be diagnosed with multiple diseases, and, because testing for infection with *N. gonorrhoeae* and *C. trachomatis* and for syphilis was routine in all patients, diagnoses were not mutually exclusive. Since neither a sexually transmitted disease diagnosis nor a single diagnosis were obligatory for inclusion in the study, the prevalence of one disease should not necessarily have influenced the prevalence of another disease.

Because the study population was composed of men presenting at a public clinic, we were unable to control for certain self-selection factors in the analysis. The frequency of exposure to sexually transmitted diseases, health-seeking behavior, and perception of disease could all influence whether or not a person presents at a clinic. Therefore, the results can be generalized only to men who, given the possibility of a sexually transmitted disease, would present at a clinic. Men who do not seek care or who seek care from clinicians in private practice are likely to be different from the men who present at clinics such as the one described here.

In addition, the study population represented a sample of all heterosexual male visits to the clinic in 1988. It is possible that the proportion of uncircumcised and circumcised men in the study population differed from the total 1988 clinic population. Of particular concern are the men who returned to the clinic in 1989 and thus were not included in the study population as a result of their charts not being archived. This potential selection bias cannot be evaluated directly because the circumcision status of all men seen at the clinic in 1988 or 1989 was not tallied in health department statistics. However, the health department does report the age and race/ethnicity distributions for all male heterosexual clinic visits. Since these two characteristics were the strong-

est predictors of circumcision status in the study population, we compared the age and race/ethnicity distributions of the study population, all clinic visits of male heterosexuals in 1988, and all clinic visits of male heterosexuals in 1989. No significant differences were observed between the three groups, indicating a similar composition in terms of age, race/ethnicity, and, presumably, circumcision status. This implied that the source of the study population, the archived clinic charts, was a reasonable reflection of all heterosexual male clinic visits in 1988. Furthermore, the age and race/ethnicity distributions did not fluctuate from year to year, and, presumably, neither did the circumcision status of heterosexual men attending the clinic. Therefore, although this potential bias cannot be dismissed, we believe it is unlikely that it had a major impact on the study results.

As with all cross-sectional studies, it is difficult to distinguish newly acquired cases from more established cases, especially for sexually transmitted diseases such as warts and herpes. However, all of the study cases were classified as new problem visits at the clinic. The reason that some individuals delayed in seeking medical care is unknown but could be due to variations in disease perception, as well as in behavior with regard to seeking health care. As a result of this limitation, we addressed only the issue of who was or was not diagnosed with a sexually transmitted disease at their initial 1988 clinic visit, not acquisition per se.

A unique feature of circumcision is that it occurs almost exclusively in infancy or early childhood in the United States. A very small percentage of men require or request the procedure as adults. Therefore, we can safely assume that in almost all of the men attending the clinic, circumcision status was determined prior to the occurrence of the disease. Thus, although a cross-sectional design was used to investigate the association between circumcision and sexually transmitted diseases, the temporal sequence of events was not in question.

The determination of circumcision status is not always straightforward because of incomplete circumcisions and foreskins that naturally retract to some degree. Information from a larger database of patients seen in the clinic from 1980 to 1989 was used to compare the recorded circumcision statuses for any patient with multiple visits. Of the 5666 patients in the database, 2266 (40%) were seen more than once. Only 13 subjects had conflicting circumcision statuses recorded. Therefore, we are confident that the clinicians consistently identified and recorded circumcision status in the vast majority of subjects.

Benefits and disadvantages of male circumcision continue to be controversial, although recent research has attempted to address pertinent health issue associated with circumcision status.[14,15] The results of this study do not show a definitive benefit of circumcision; although uncircumcised men were more likely to have syphilis and gonorrhea, circumcised men were more likely to have genital warts and equally likely to have nongonococcal urethritis and genital herpetic lesions. □

Employment Status and Depressive Symptoms in Middle-Aged Women: A Longitudinal Investigation

Joyce T. Bromberger, PhD, and Karen A. Matthews, PhD

ABSTRACT

Objectives. This study investigated the psychological effects of paid employment and nonemployment, cross-sectionally and longitudinally, in 541 middle-aged women.

Methods. Women were seen for an extensive baseline evaluation and were reevaluated in an identical manner 3 years later. They were divided into four "synthetic" cohorts, based upon employment status at these two assessments.

Results. At baseline, nonemployed women reported higher levels of depressive symptoms than employed women, with nonemployed women with less education, low support from family and friends, or low marital satisfaction the most symptomatic. Symptoms decreased in women who were nonemployed initially but employed at the later exam; in all other groups, symptoms increased. Unlike the cross-sectional findings, however, the longitudinal findings showed that women who were nonemployed at baseline and had low levels of education, social support, or marital satisfaction did not benefit more from subsequent employment than did their counterparts who had high levels of these factors.

Conclusions. New paid work may have a positive effect on mood for middle-aged women. However, given the contradictions between our cross-sectional and longitudinal results, caution should be exercised in drawing conclusions from cross-sectional studies that likely confound employment status, symptoms, and moderating variables. (*Am J Public Health.* 1994;84:202–206)

Introduction

In the last 30 years, the number of women participating in the labor force has increased dramatically.[1,2] According to recent census information, 57% of women are currently in the civilian labor force, compared with 38% in 1960.[2] Whether there are positive or negative consequences concomitant with this trend is of central concern to public health. According to the "scarcity" hypothesis, employment adds another major role for women (besides homemaker and mother) that inevitably leads to role strain, overload, and psychological problems.[3] The alternative "enhancement" hypothesis argues that the occupancy of multiple roles enhances feelings of security and self-worth, and increases sources of gratification and social support[3]; thus, employment should improve women's mental health.

Cross-sectional studies of women's employment have shown either a positive or a null effect for women in general[4–7] and differential effects for certain subgroups of women: employment has been found to be more beneficial for women of low socioeconomic status,[4,8,9] for women whose husbands share responsibility for household chores or child care,[10–12] for married women in unsatisfying marriages,[4,13] and for women who report high job satisfaction compared with their appropriate counterparts. The correlational nature of cross-sectional research, however, precludes an assessment of the direction of effects in these observed relationships.

Two longitudinal investigations are relevant here. Among women aged 40 to 45 who were (1) unmarried or (2) married and Black, those who were out of the work force at the start of the study reported a greater increase in health problems over 5 years than those who were not.[14] Among young army wives, those who were not employed when the study began but were employed 6 months later had the largest overall increase in general psychological well-being when compared with women who were either employed or not employed at both times, or with women who were employed initially but not later.[15] Those who were employed at both times reported a modest decrease in well-being.

The present longitudinal study evaluated the relationship between change in employment status and change in depressive symptomatology in middle-aged women. Based on the "enhancement" theory, we anticipated that paid employment may be particularly important for the psychological and emotional well-being of women in midlife because it offers them new options in the face of the biological and social changes known to accompany middle age.[16] We specifically hypothesized that employment would be emotionally beneficial because it increases financial resources and provides additional sources of personal worth, gratification, and social support. Furthermore, the greatest psychological gains from employment would be experienced by women with few initial resources (i.e., low education and low social supports), by married women with unsatisfying marriages, and by women for whom paid work would not function as an overload (i.e., women with low household/child responsibilities). At the same time, working women who had positive job experiences (e.g., high job satisfaction) at baseline would be most negatively affected by subsequent nonemployment.

This paper was accepted September 20, 1993.

Finally, the results from this longitudinal study were expected to replicate the results of our initial cross-sectional analyses.

Methods

Subjects

Between 1983 and 1985, 541 middle-aged women were recruited to participate in a prospective investigation of the effects of menopause on behavioral and biological cardiovascular risk factors.[17] Randomly selected women aged 42 to 50 who lived within selected zip codes in Allegheny County (including Pittsburgh, Pa) and had driver's licenses were sent a letter of invitation. Of the 2405 women subsequently contacted by telephone, 901 were eligible for inclusion, and of these, 541 (60%) agreed to participate. To be eligible for the study, participants had to have had menstrual bleeding within the prior 3 months; no surgical menopause; diastolic blood pressure below 100 mmHg; and no medications known to influence the biological risk factors under study, including psychotropic agents. Participants were better educated than nonparticipants.

At study entry, 411 of the women were employed and 129 were nonemployed; 3 years later, 524 of these women (97%) participated in a follow-up examination. One woman was excluded at baseline because she did not complete the Beck Depression Inventory. Based upon employment status at the baseline and 3-year assessments, women were divided into four "synthetic" cohorts: (1) always employed (employed at both visits), (2) always nonemployed (nonemployed at both visits), (3) newly nonemployed (employed at baseline and nonemployed at 3-year exam), and (4) newly employed (nonemployed at baseline and employed at 3-year exam).[18] Among those always employed, 96% were continuously employed throughout the study period; among those always nonemployed, 71% were continuously nonemployed.

The sociodemographic characteristics of these groups are shown in Table 1. Those who were always employed were more likely to be unmarried than the others and to be better educated than those who were always nonemployed; the latter group had more married women and fewer women with advanced degrees than all the other groups. Marital status and educational attainment were included as covariates in the analyses reported below. Perimenopausal and postmenopausal women were evenly distributed among the employment groups.

Procedures

After interviews were conducted to determine eligibility and verify blood pressure levels, all participants were seen at a university clinic for a baseline assessment and, approximately 3 years later, for another evaluation. As part of both assessments, the women completed—in addition to measures of biological characteristics and health behavior—a self-report inventory providing data on employment status, job characteristics, depressive symptomatology, and various other psychosocial factors. Following the 3-year exam, the women were requested by letter to complete an employment history questionnaire.

Measures

Outcome variable. Depressive symptoms experienced during the 2 weeks prior to the clinic visit were measured by the Beck Depression Inventory. This 21-item self-report inventory rates the extent to which a symptom has been present; rates range from 0 (not at all/a little) to 3 (a lot/almost all the time). It has been shown to have good reliability and validity.[19] In the present sample, internal reliability was very good ($\alpha = .85$). Beck scores were subjected to a logarithmic transformation because of its skewed distribution in the present sample.

Independent variables. For conceptual and analytic consistency, all moderators were treated as categorical variables, with median splits used unless otherwise indicated. Less education refers to some college or less, and more education refers to a college or advanced degree.

Employment variables consisted of four job characteristics: job satisfaction, use of skills, job future ambiguity, and boss support. The first three were derived from a factor analysis of a 15-item questionnaire taken from an inventory developed by Caplan and associates[20] and modified by Cottington.[21] All factors demonstrated good internal reliability (αs = .69 to .82). Boss support was assessed by a 7-item yes/no scale that was developed in the Framingham Heart Study and yielded an alpha coefficient of .82 in that study.[22] In the present sample, the alpha coefficient was .70.

Married women indicated their level of satisfaction with seven aspects of their marital relationship ranging from 0 (not at all satisfied) to 3 (very satisfied). A factor analysis of these items yielded only one factor, which explained 60.1% of the variance and had very good internal reliability ($\alpha = .87$). Women then indicated how the responsibilities for seven areas of household and family life were divided between themselves and their husbands; such responsibilities were deemed (1) largely their husband's, (2) about equal, or (3) largely their own. A factor analysis of

TABLE 3—Mean (Log Transformed) Beck Depression Inventory Scores, Adjusted for Education and Marital Status, of Four Employment Groups

Examination	Always Employed	Always Nonemployed	Newly Nonemployed	Newly Employed
Baseline	.56 (4.2)	.61 (5.0)	.56 (4.1)	.71 (6.4)
3rd year	.60 (4.8)	.68 (6.4)	.60 (4.7)	.58 (5.9)

Note. The numbers in parentheses are the untransformed mean Beck Depression Inventory scores, adjusted for education and marital status.

these areas generated two factors; only one had good internal reliability ($\alpha = .76$) and included responsibilities for household chores, children, parents and relatives, and the happiness of the family.

Two types of social support were measured: perceived and structural. The former was determined from the appraisal support subscale of the Interpersonal Support Evaluation List, which has good internal and test-retest reliability.[23] This subscale assesses the subject's perception of the availability of someone to talk to about her problems. An alpha coefficient of .80 in our sample was found. Because of the skewed distribution of perceived support in this sample, an approximately one-third, two-thirds split was used for low and high support, respectively. Structural support consisted of two questions asking the subject how many (1) friends/neighbors and (2) family members not living with her she has kept in touch with during the previous 6 months? The variables were dichotomized in a one-quarter, three-quarters split for low and high support.

Using a modified version of the Pilkonis Life Event Schedule,[24,25] women indicated whether they had experienced any of 54 events in the 6 months prior to their 3-year clinic visit. They then indicated what the three most important events were and how stressful (not very, moderately, very) each one was for them. Stress was evaluated as a dichotomous variable: present (very stressful important event) or absent (no important events or not very/moderately stressful important event).

Results

Cross-Sectional Association between Employment Status and Depressive Symptoms

One-way analysis of covariance (ANCOVA) showed that, at study entry, nonemployed women had a significantly higher mean Beck Depression Inventory score than did employed women ($F[1, 520] = 5.44$; $P = .02$). A planned contrast procedure, in which a two (employment group: employed vs nonemployed) by two (low on factor vs high on factor) ANCOVA was followed by the calculation of a contrast F,[26] tested the hypothesis that women who reported a low level of education, perceived support, family support, friend support, or marital satisfaction (married only) and who were nonemployed would show higher Beck scores than all other women. All Fs were significant, thus confirming our hypothesis and replicating previous cross-sectional results (see Table 2).

Relationship between Change of Employment Status and Change in Depressive Symptoms

A planned contrast, in which a four (employment group: always employed, always nonemployed, newly nonemployed, and newly employed) by two (examination) repeated measures ANCOVA on the Beck scores measured at baseline and at 3-year follow-up was followed by the calculation of two contrast Fs, tested the hypothesis that the newly nonemployed would report an increase in symptoms from baseline to the 3-year exam, the newly employed would show a decrease, and both the always employed and the always nonemployed would report similar levels at both times. Results indicated an absence of support for our specific hypothesis.

Nonetheless, the initial ANCOVA showed a significant group-by-time interaction ($F[3, 520] = 3.31$; $P < .02$), indicating that the amount of change in depressive symptomatology over time differed among the four groups. The symptom levels increased over time for three of the groups while they decreased for one, the newly employed (Table 3). A follow-up repeated measures ANCOVA comparing the newly employed with the other three groups combined showed a significant group-by-time interaction ($F[1, 522] = 9.73$; $P < .007$ [Bonferroni adjusted]), suggesting that new employment was beneficial. This effect remained when the baseline Beck score was included as a covariate.

Influence of Psychosocial and Job Characteristics on Change in Depressive Symptoms

Planned contrasts also evaluated how the characteristics of the woman and

her job affected the relationship between change in employment status from baseline to 3-year exam and change in depressive symptom level. Because of the number of ANCOVAs conducted (n = 32), $P < .01$ was used as our significance level. Results were all nonsignificant.

Five characteristics of the women assessed at baseline did influence Beck scores, irrespective of employment status. Women's perception of low support, low family support, low marital satisfaction (married only), low job satisfaction, and negative job future at the beginning of the study were significantly associated with high symptom levels at the same time as well as 3 years later (Table 4). These findings were consistent with those found in previous literature.[10,27-29]

TABLE 4—Mean (Log Transformed) Beck Depression Inventory Scores, Adjusted for Education and Marital Status,[a] According to Baseline Psychosocial Characteristics

Characteristic	Examination	High	Low	*F* Value on High/Low Characteristic from Analysis of Covariance[c]
Perceived support	Baseline	.53 (3.8)	.76 (7.3)	
	3rd year	.53 (4.0)	.78 (8.2)	32.7
Family support	Baseline	.57 (4.2)	.74 (7.3)	
	3rd year	.57 (4.6)	.75 (8.0)	13.0
Marital satisfaction	Baseline	.43 (2.6)	.71 (6.3)	
	3rd year	.46 (3.3)	.72 (7.0)	38.7
Job satisfaction[b]	Baseline	.46 (2.9)	.67 (5.5)	
	3rd year	.53 (3.9)	.70 (5.9)	13.7
Job future[b]	Baseline	.44 (2.8)	.64 (5.1)	
	3rd year	.49 (3.4)	.70 (5.8)	16.4

Note. The numbers in parentheses are the untransformed Beck Depression Inventory scores, adjusted for education and marital status, as in log transformed analyses.
[a]Analysis for marital satisfaction was conducted for the married women and was adjusted for education only.
[b]Analyses conducted for those employed at baseline.
[c]All values are significant at $P < .001$.

TABLE 5—Mean (Log Transformed) Beck Depression Inventory Scores, Adjusted for Education and Marital Status, of Employment/Stress Groups

	Newly Employed		All Others	
Examination	No Stress	Stress	No Stress	Stress
Baseline	.67 (5.9)	.78 (7.4)	.52 (3.7)	.67 (5.5)
3rd year	.46 (4.7)	.84 (8.4)	.55 (4.1)	.76 (7.0)

Note. The numbers in parentheses are the untransformed mean Beck Depression Inventory scores, adjusted for education and marital status.

Life Stress and Employment

The well-established association between life stress and depressive symptoms and disorder[30-32] led us to examine if stress might explain the difference in Beck scores between the newly employed and the other women. The proportion of women who reported a stressful event in each employment group was approximately the same: 30%. Results of a two (newly employed vs all other women) by two (presence vs absence of stress) ANCOVA with repeated measures performed on the Beck scores showed a significant main effect for stress on symptoms ($F[1, 518] = 13.99$; $P < .01$). The three-way interaction between time, stress, and group was of borderline significance ($F[1, 520] = 2.90$; $P < .10$). Beck scores decreased for the newly employed women who did not report a stressful event but tended to increase for all the other groups (Table 5). Thus, our exploratory analyses suggest that the decrease in Beck scores for the newly employed women might be restricted to those not experiencing a stressful life event in the 6 months prior to their 3-year exam.

Discussion

Our cross-sectional analyses were consistent with those of other cross-sectional studies[5,33,34] in showing that women who work are psychologically better off than those who do not. Also consistent with previous cross-sectional research, nonemployed women with low perceived support, family support, friend support, education, or marital satisfaction were more symptomatic than those who were high on these characteristics. Unexpectedly, the longitudinal analyses did not reveal the same picture. Irrespective of the women's psychosocial characteristics at baseline, depressive symptoms decreased among the newly employed and increased for the others.

Exploratory analyses indicated that the newly employed women who reported no stress at the 3-year exam were the only subjects to show, on average, a decrease in depressive symptoms; all other women showed either no change or an increase in symptoms. Perhaps under conditions of low life stress, employment has the potential for enhancing mental health, whereas under stressful life circumstances, the positive effects of employment may be suppressed. Although a few studies have observed a significant relationship between work and/or family stresses and psychological symptomatology among employed women,[35,36] little is known about the combined and differential effects of various stressful events or situations for the employed and nonemployed women. Further studies are needed to examine specifically the interactive and additive effects of stress and employment/nonemployment on women's mental health.

The discrepancy between the cross-sectional results and those of our longitudinal analyses highlight the methodological limitations of cross-sectional research. An important advantage of our design is that the variables we examined as potential moderators of the employment-symptom relationship were assessed at least 2 years prior to any change in employment status. Thus, these variables could not be confounded with subsequent symptoms as they probably were with current ones. Although the contradictions between the cross-sectional and longitudinal results could be due to poor measurement or chance findings in the former, this is unlikely since our cross-sectional findings were highly significant and consistent with previous cross-sectional literature. Moreover, three of the measures used had previously established good reliability (per-

ceived support, educational level) or internal reliability (perceived support, marital satisfaction) in the study sample. Therefore, we conclude that the significant interactions between the independent variables and employment status obtained in the cross-sectional analyses probably reflect the characteristics of those women who are unable to seek and maintain employment and thus are not a true effect for employment.

Because our study was originally designed to assess the effects of menopause on cardiovascular risk factors, we had no information about why the women were or were not working, what their expectations of work were, and what they and their spouses thought about women who worked. We also had no information about the psychiatric histories of the women, an important determinant of current psychiatric distress and disorder. Nonetheless, we did have ample data—more than many studies—regarding other characteristics of the women and their work, and the data were prospective in nature.

In conclusion, new employment appears to have an acute positive effect on mood. Despite the many analyses we conducted and our own cross-sectional results, when examined prospectively, no subgroups seem to benefit more than others from new employment. Post hoc analyses suggest that for middle-aged, predominantly middle-class women, new employment might be especially beneficial among those who have not experienced a stressful life event in the previous 6 months. Consistent with the enhancement theory of multiple roles, employment is not detrimental to women's psychological well-being. □

Providing Medical Care to Methadone Clinic Patients: Referral vs On-Site Care

Annie Umbricht-Schneiter, MD, David H. Ginn, MD, Katherine M. Pabst, CRNP, MPH, and George E. Bigelow, PhD

ABSTRACT

Objectives. Intravenous drug users are at high risk for medical illness, yet many are medically underserved. Most methadone treatment programs have insufficient resources to provide medical care. The purpose of this study was to test the efficacy of providing medical care at a methadone clinic site vs referral to another site.

Methods. Patients with any of four target medical conditions were randomized into an on-site group offered medical care at the methadone treatment clinic and a referred group offered medical care at a nearby clinic. Entry to treatment and use of medical services were analyzed.

Results. Of 161 intravenous drug users evaluated, 75 (47%) had one or more of the target medical conditions. Fifty-one were randomized. In the on-site group (n = 25), 92% received medical treatment; in the referred group (n = 26), only 35% received treatment.

Conclusions. Providing medical care at a methadone treatment program site is more effective than the usual referral procedure and is a valuable public health intervention. (*Am J Public Health.* 1994;84:207–210)

Introduction

Intravenous drug users are at high risk for medical problems.[1–7] A substantial portion of this population consults physicians only for catastrophic health crises (mostly through emergency rooms); they also tend to show poor compliance with treatment.[8] Alternative approaches to health care delivery to intravenous drug users are needed. Integrating medical services into addiction treatment clinics has the potential for improving the prevention and treatment of diseases in this population,[9] and methadone treatment is effective in decreasing high-risk behaviors such as intravenous drug use and needle sharing. The acquired immunodeficiency syndrome (AIDS) epidemic has renewed public health interest in methadone treatment and in the need for delivering effective medical care to intravenous drug users. Some studies have shown that treatment of human immunodeficiency virus (HIV) infection or tuberculosis is feasible at methadone treatment clinics[10]; however, the relative efficacy of such interventions has not been documented.

Providing comprehensive medical care at a methadone treatment clinic offers an opportunity to screen for diseases and promote health education and behavioral changes. When patients come to the clinic to receive methadone, their compliance with other treatments can be promoted and/or directly supervised.

This study assessed the prevalence of four target medical conditions in a population of intravenous drug users seeking treatment for their addiction and compared the effectiveness of two methods for addressing these conditions: direct medical treatment at the addiction treatment clinic site (on-site care) and referral to a medical clinic (referred care), which is the usual procedure.

Methods

Recruitment, Eligibility, and Randomization

The study site was a hospital-based methadone treatment research clinic in southeastern Baltimore. The patient population consisted of opioid-dependent drug users; many were also using other drugs, mainly alcohol and cocaine. Patients received a medical examination on admission to methadone treatment. Medical care was free for the duration of the study if patients agreed to participate in a randomized trial that involved receiving medical care at the drug treatment site (on-site group) or being referred to a nearby medical clinic (referred group). Participants provided written informed consent. Those who needed further medical care for any of four target conditions and who had no primary care physicians were randomized. The target conditions were hypertension, purified protein derivative conversion (tuberculosis exposure), positive HIV serology (asymptomatic), and acute sexually transmitted diseases. At randomization, all patients were seen by the on-site medical staff and informed of their medical condition, need for treatment, and need for HIV posttest counsel-

TABLE 1—Demographic, Social, and Diagnostic Characteristics of the Two Groups

	On-Site Group (n = 25), No.	Referred Group (n = 26), No.
Men	17	20
Non-Whites	16	19
Working status		
Working	5	6
Unemployed	17	17
Disabled	1	2
Marital status		
Single	11	10
Married	3	7
Divorced or separated	8	9
Insurance status		
Medical assistance	10	10
Private	2	7
None	13	8
Source of care		
Emergency room	19	17
Continuous care[a]	4	7
Reason for initial referral[b]		
HTN	4	3
PPD	7	9
HIV positive	7	4
STD	7	10
Distribution of diagnoses[b]		
HTN	4	3
PPD	8	14
HIV positive	7	4
STD	9	13

Note. HTN = hypertension, PPD = purified protein derivative, HIV = human immunodeficiency virus, STD = sexually transmitted disease.
[a]Continuous care by private physician, hospital clinic, or health maintenance organization.
[b]Patients could have several diagnoses but only one reason for initial referral.

ing. Patients randomized to the on-site group were treated immediately, or a follow-up appointment was arranged. The medical staff was actively involved in offering care to patients. Patients randomized to the referred group were instructed to contact a medical clinic located on the same campus as the addiction clinic, received written instructions describing the clinic location, and were given the telephone number of the clinic. The referred patients were responsible for obtaining an appointment at the medical clinic, where a physician was available twice a week; there was no waiting list, and appointments could be obtained within 4 days. To facilitate interactions with personnel at the medical clinic and ensure proof of coverage, all administrative information was collected by the research assistant at randomization and communicated to the clinic. To avoid economic confounds, the study covered the cost of medical care, including medications, for 3 months after randomization.

Patients were interviewed by a research assistant at 4 and 8 weeks after randomization. If a patient had not received medical treatment by week 4, the on-site medical staff stressed the importance of such treatment. A patient remaining untreated at week 8 was considered a treatment failure. For those patients still enrolled in drug treatment, medical care was then offered on-site. This "rescue treatment," of which patients were unaware, was arranged for ethical reasons. (Rescue treatment was offered to patients with acute sexually transmitted diseases at week 4).

At the end of the study, patients were referred to medical clinics elsewhere. Patients without insurance at enrollment were assisted in applying for medical assistance or other benefits.

Medical Evaluation

Hypertension. Patients with a diastolic blood pressure of 100 mm Hg or more were randomized. Patients with a diastolic blood pressure of 95 to 100 mm Hg were randomized if their blood pressure remained elevated after the first week of drug treatment.

Tuberculosis exposure. Patients with no prior history of tuberculosis exposure were tested with five standard tuberculin units (by intradermal injection) and examined 48 hours later. A reaction was considered positive if an induration of 5 mm or more was noted. (This represents the Centers for Disease Control recommendation for individuals who are HIV positive; because HIV status was unknown, these guidelines were extended to all patients.)[11,12]

Sexually transmitted diseases. Rapid plasma reagin (RPR) was obtained. In men, a first-stream urine was tested for leukocyte esterase and pyuria (more than five white blood cells per high-power field). Patients with positive urine were randomized, and a urethral sample was then analyzed for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* by DNA probe.[13] Women were screened with a Pap smear and tested for *Candida albicans, Trichomonas vaginalis, N. gonorrhoeae,* and *C. trachomatis.* Although we strongly stressed the importance of the pelvic examination, women were allowed to refuse it.

HIV. Written informed consent was obtained after pretest counseling. If patients accepted testing, their blood sample was tested confidentially. Patients with symptomatic HIV infection (AIDS-related complex, AIDS) were referred to specialized clinics for care and were not randomized.

Addiction Treatment

Patients were enrolled in combined pharmacological and counseling treatment protocols for their drug addiction. The details of these protocols are beyond the scope of this paper.

Data Collection

Medical charts of newly admitted patients were reviewed weekly. A flow sheet was maintained to record the medical conditions and treatment assignment. The patient's counselor received a portion of the flow sheet to help coordinate addiction and medical treatment.

Enrollment in medical care was recorded, by patient interview and chart review, at 4 and 8 weeks after randomization. Primary outcome measures were number of visits per patient (visits for other medical conditions were not counted) and whether patients complied with the treatment plan (treatment rate per diagnosis).

Statistical Analysis

Comparisons between the two groups were made with *z* tests for proportions on dichotomous variables; *t* tests were used on continuous variables.

Results

Prevalence of the Target Medical Conditions

Of 161 patients evaluated, 75 had one or more of the target conditions: 12 had hypertension, 26 evidenced purified protein derivative conversion, 24 had positive HIV serology (27 [18%] refused testing), and 29 had sexually transmitted diseases (14 [25%] of 57 women refused pelvic examination).

Patient Characteristics

The characteristics of the 51 patients who were randomized are shown in Table 1. There were no significant differences between the two groups on any of the listed variables or in addiction treatment modality.

Enrollment in Medical Treatment

Of 25 patients randomized on-site, 23 (92%) enrolled in medical treatment and

complied with medical recommendations. Of 26 patients referred off-site, only 9 (32%) enrolled in medical treatment (8 enrolled at the assigned off-site clinic and 1 called a physician for a prescription). The difference between the two groups was statistically significant ($P < .001$).

Table 2 describes the medical care received by the two groups. All patients in the on-site group were seen at least once regarding their medical condition(s), 23 accepted treatment, and 19 (76%) had one or more additional follow-ups. The average number of visits per patient was 3.1 (SD = 1.8); the treatment rate per diagnosis was 88%. In the referred group, 8 patients (31%) were seen once at the off-site medical clinic and 1 obtained treatment elsewhere; of 5 patients scheduled for follow-up, 1 returned. The treatment rate per diagnosis was 28%.

The greater overall efficacy of the on-site procedure was corroborated in analyses within each of the four individual target medical conditions.

Hypertension. Four patients in the on-site group were successfully treated with normalization of their blood pressure (three with behavioral treatment, one with pharmacological treatment). Of the three patients in the referred group, two were started on antihypertensive therapy but did not return.

Tuberculosis exposure. Of 8 patients in the on-site group, 1 remembered prior tuberculosis treatment as a child. Of the 7 remaining patients, 6 obtained a chest x-ray. Chemoprophylaxis was indicated and administered at the methadone window to 1 of them. In spite of three medical visits, 1 patient did not comply with the request for chest x-ray. Of 14 patients in the referred group, 1 had a history of previous treatment. Of the remaining 13, only 3 obtained a chest x-ray. The rescue treatment allowed an additional 3 patients to be evaluated on-site, and 1 of them received chemoprophylaxis.

HIV. Of seven patients in the on-site group, five gave blood for the CD4 cell count, and two patients meeting criteria for retroviral therapy received zidovudine (AZT). Two patients refused further evaluation; one of them was seen seven times for intensive counseling, and both were referred to HIV clinics. Of the four patients in the referred group, only one came for the CD4 cell count. This patient's follow-up was interrupted involuntarily (by incarceration).

Sexually transmitted diseases. Of 9 patients randomized to the on-site group, 8 were treated successfully (1 twice, after reexposure). One patient with secondary syphilis completed appropriate therapy, and 1 patient with treated syphilis did not need further care. Of the 13 patients randomized to the referred group, 4 received treatment. Another patient with treated syphilis did not require treatment. Two other patients received rescue treatment on-site.

TABLE 2—Treatment Information for the Two Groups

	On-Site Group (n = 25)	Referred Group (n = 26)	P
No. of patients seen one or more times	25	8	<.001
No. of patients seen two or more times	19	1	<.001
No. of visits per patient, mean ± SD	3.1 ± 1.8	0.4 ± 0.6	<.001
Treatment rate, %[a]	88	28	<.001

[a]The denominator is the number of diagnoses rather than the number of patients.

Discussion

More than 45% of intravenous drug users seeking methadone treatment presented with a condition requiring medical care. When on-site medical care was available, more than 90% received treatment; when referred medical care was available, only 35% received treatment.

Prevalence of Medical Conditions

Among intravenous drug users seeking addiction treatment, we found that half had a condition, often unknown to them, that required medical care. This is a conservative assessment, because our study recorded only four target medical conditions. Three of these conditions (tuberculosis, sexually transmitted diseases, and HIV infection) currently represent serious public health threats because they reach epidemic proportions not only among intravenous drug users but also among their close contacts. Because of their asymptomatic course, it is important that they be detected and treated in a timely and effective manner.

Although not reported in this study, we found that many more patients suffered from other medical conditions such as soft-tissue infections, liver damage, respiratory diseases, and anemia. For ethical reasons, these conditions were treated by the on-site medical staff.

Efficacy of On-Site Care

In the on-site group, 92% of intravenous drug users entering addiction treatment received medical care, with a treatment rate per diagnosis of 88%. In comparison, in the referred group (with optimal referral conditions), only 35% of patients received medical care for the same conditions, with a treatment rate per diagnosis of 28%.

The difference in enrollment for medical care between the two groups may reflect, in part, a difference in providers' behavior rather than patients' behavior. In the drug treatment program, the medical team used nontraditional doctor–patient approaches: accepting unscheduled visits (initiated when "spotting the provider in the hall") and rescheduling several times for missed appointments. Coordination with the nurses dispensing methadone was of prime importance: they reminded patients of their medical appointment and, when needed, "held" the methadone temporarily until patients reported to the medical provider. Furthermore, compliance with medical treatment could be fostered by administering other medications along with the methadone. No patient was coerced into accepting medical treatment, but avoiding interaction with the medical staff was difficult.

We noted that patients used the on-site medical services extensively for other conditions or for health education. This suggests that intravenous drug users are interested in health care when it is available.

The presence of medical providers at the addiction treatment clinic site alleviated some of the burden usually carried by nurses or counselors alone. These providers assisted in the evaluation of acutely ill patients and reduced the need for referral to local emergency rooms.

Providing medical care to intravenous drug users remained a challenge, even at an addiction treatment clinic site; however, the study showed that this type of health care delivery resulted in high enrollment in medical care and an excellent treatment rate, whereas the usual referral process resulted in an unacceptable loss of patients to medical care.

While the emphasis of the present discussion is that methadone clinics can

enhance medical treatment efficacy, it should be noted that recent research[14] also suggests the converse: providing medical and psychosocial services can enhance the efficacy of addiction treatment. Given the current infectious disease epidemics, intravenous drug users should have increased access to methadone treatment providing comprehensive care.

This study is, to our knowledge, the first controlled randomized trial to test the efficacy of providing primary medical care at an addiction treatment site. The high prevalence of medical conditions in this population may be sufficient rationale, at least on a humanitarian basis, to provide medical care at addiction treatment clinics. The superior efficacy of this approach, as documented here, further strengthens this rationale. Additional study is needed (e.g., assessments of emergency room visits or hospitalizations) to evaluate the cost-effectiveness of providing medical care at addiction treatment sites.

Barriers to Referred Medical Care

For several reasons, intravenous drug users are unlikely to use traditional medical services. Many fear discriminatory or hostile behavior from the medical staff in general clinics or hospitals.[15,16] If the drug users are hospitalized, their methadone treatment may be discontinued and the resulting withdrawal symptoms not adequately treated.

Many fear the stigma of being labeled HIV infected if seen in an addiction treatment clinic.

Medical practices tend to avoid referrals from drug treatment clinics. Four medical practices were asked to serve as referral sites for this study, and, although occasional individual physicians (with some training in addiction medicine) agreed to participate, all four practices refused. This was especially notable given that the study guaranteed fee payment, including a fee for "missed appointments." This reluctance to provide care to drug users appeared related to concerns about the behavioral stereotypes of the population, as well as possible economic risks after the conclusion of the study.

For intravenous drug users entering drug abuse treatment, the active planning required to obtain health care (such as scheduling an appointment and arranging for timely transportation) involves a level of structured behavior that is a goal of, rather than a prerequisite for, addiction treatment. Medical and addiction clinics rarely coordinate opening hours, thus complicating the patient's task further.

If drug treatment clinics are to provide screening for diseases such as tuberculosis, HIV infection, and sexually transmitted diseases (as federal guidelines currently recommend), they should also be able to provide medical treatment; issues of confidentiality restrict communication between providers, and patients often misunderstand their medical conditions.

Finally, this study featured an optimal referral process; detailed oral and written information on how to contact the clinic was provided, and all monetary obstacles were removed. Still, only 35% of the referred group enrolled in medical care. In reality, compliance with the usual referral procedure is probably less successful, because patients may lack adequate health care coverage (in our program, 40% of the patients had no insurance).

Conclusions

This study demonstrated a high prevalence of concurrent medical conditions requiring further care among intravenous drug users entering addiction treatment. When medical care was available on-site at the addiction treatment clinic, nearly all received care. When medical care was available through the usual referral procedure, few received care. These data argue for the effectiveness and public health value of providing medical care resources within addiction treatment clinics. □

The Relationship between Mortality and Intensity of Inpatient Alcoholism Treatment

ABSTRACT

Objectives. Previous studies have examined mortality in alcoholics receiving extended inpatient alcoholism treatment, but few have investigated less intense treatment. This study examined mortality within 3 years after discharge from varying intensities of inpatient alcoholism treatment.

Methods. Using the computerized database of the Department of Veterans Affairs, we identified men participating in varying intensities of inpatient alcoholism treatment and followed them for 3 years after discharge. Adjusted mortality rates were computed and survival analysis was performed to assess the risk of death, adjusting for factors that may be related to mortality.

Results. The death rate was lower for men who completed extended formal inpatient treatment than for those who began, but did not complete, inpatient treatment or those who underwent short detoxification. Differences among the treatment groups remained after age, race, marital status, and disease severity were controlled.

Conclusions. These results suggest that extended formal inpatient alcoholism treatment is associated with a lower risk of death than less intense forms of inpatient treatment. (*Am J Public Health.* 1994;84:211–214)

Introduction

The increased risk of premature death among alcoholics has been well documented;[1,2] potential life lost has been estimated to be about 15 years.[3] The risk of mortality for alcoholics has been reported to be two to three times that of the general population,[4,5] with more than sevenfold increases in mortality in some groups.[6,7]

Several studies have used hospital admission data to identify potential alcoholics. These patients, however, were not exclusively limited to those being treated for alcoholism. Rather, such analyses have included patients discharged from mental hospitals[5,8] or psychiatric units of general hospitals[6] with diagnoses indicating alcoholism but not necessarily representing formal alcoholism treatment. Other studies have included persons whose charts indicated the presence of alcohol-related problems but who were hospitalized for medical or surgical reasons.[9] As a result, the subsequent mortality of these patients may have been influenced by the medical diagnosis for which the patient was admitted, the number and severity of medical problems, the type of care provided during the hospitalization, or the type of hospital from which the patient was enrolled.[9,10]

Although alcoholism treatment that is less intense than extended inpatient treatment is available, patients receiving such care are often not included in follow-up studies. Thus, relatively little is known about mortality in treated alcoholics participating in programs of varying lengths and intensities of treatment. In this study we examined the mortality of a large sample of alcoholics who completed extended formal inpatient alcoholism treatment or less intense forms of inpatient alcoholism treatment. A large group of alcoholic patients hospitalized for medical, surgical, or psychiatric problems was included for comparison.

Methods

Identification of the Sample

The subjects in this study were identified through the Department of Veterans Affairs (VA) computerized database, the Patient Treatment Files. Each file contains discharge information for all patients treated at any VA facility in the country during a given fiscal year.

Each alcoholic was placed into one of three treatment groups on the basis of treatment received during fiscal year 1987: (1) patients who completed extended formal inpatient alcoholism treatment (n = 28 060); (2) patients who underwent at least 6 days of extended formal inpatient alcoholism treatment but who did not complete the treatment (n = 10 922); or (3) patients admitted for short detoxification lasting 5 days or less (n = 9424). A fourth group of hospitalized alcoholics who received no direct alcoholism treat-

Race		
Caucasian	1.00	
Non-Caucasian	0.98	0.92, 1.05

ment was identified for comparison purposes (n = 26 261). These patients had primary diagnoses that were medical or psychiatric in nature and secondary diagnoses indicating chronic alcoholism. Details regarding sample selection are published elsewhere.[11] Because of the small number of female alcoholics treated in the VA system, the study population was limited to men.

Information on patients not using VA services at the end of 3 years, including name, social security number, date of birth, gender, and state of last residence, was sent to the National Death Index for comparison with the Index's files. The National Death Index maintains a computerized database of deaths recorded by state vital statistics offices and submitted to the National Center for Health Statistics. Data received from the Index were screened to identify matches for patients who died within 3 years of discharge from the index hospitalization. Any patients not identified through the Index records were assumed to be alive at the end of the 3-year follow-up period.

Data Analysis

The number of deaths and the number of years each person was alive following the treatment episode were tabulated to compute crude and adjusted mortality rates. Age-specific mortality rates were calculated for each racial group by dividing the number of deaths in a given age group by the total person-years in that age group. Mortality rates were then adjusted directly,[12] with the entire male population of the United States enumerated in the 1990 census used as the standard population.[13] Age-adjusted, race-specific rates were initially computed; however, because the age-adjusted mortality rates for Caucasians and non-Caucasians did not differ, they were combined to provide age- and race-adjusted mortality rates.

A survival analysis examined the time to death for the three treatment groups, controlling for potential confounding variables, including age, marital status, race, and severity of alcohol-related complications. Age was measured in 10-year intervals; marital status was coded as married or not married. Because of the relatively small number of individuals in some of the racial/ethnic groups examined, all non-Caucasians were combined. The severity of medical-related complications of alcoholism was determined by an approximation of the disease staging methodology,[14] allowing categorization into one of three stages of disease, ranging from disease with minimal severity and no complications to disease involving multiple physiological systems. The reference group was composed of unmarried Caucasian men younger than 30 years of age who completed extended formal inpatient treatment.

Results

More than 8% of the treated alcoholics (4069/48 416) died within 3 years following discharge from the index treatment episode. As described in Table 1, 7.1% of the group that completed extended formal alcoholism treatment died. Mortality in the incomplete treatment group (9.5%) and the short detoxification group (11.2%) was higher than for those who completed extended formal treatment. In the group of alcoholic patients who received no alcoholism-specific treatment in fiscal year 1987, 23% died.

The crude death rates ranged from 24.35 per 1000 person-years for the completed treatment group to 39.60 per 1000 person-years for those who underwent short detoxification (Table 1). Similarly, the age- and race-adjusted mortality rate increased with a decreasing amount of alcoholism-specific treatment and was highest in the group that received the least treatment, the short detoxification group (35.12 deaths per 1000 person-years). In contrast, those who received no direct alcoholism treatment had an age- and race-adjusted mortality rate of 56.72 deaths per 1000 person-years.

Results of the survival analysis for patients in the three treatment groups are presented in Table 2. The higher mortality rates observed in the less intense alcoholism treatment groups presented in Table 1 were reflected as increased risk ratios when these groups were compared with those who completed extended formal inpatient treatment. Men in the incomplete treatment group had a 24% elevation in mortality risk, whereas the risk ratio in the short detoxification group was 1.44.

There was an increasing risk of death with increasing age. Men 70 years of age and older experienced a greater than 10-fold increase in the risk of dying during the 3-year period. The presence of complications of alcoholism, as measured by disease severity, increased the risk of dying by 22% for those whose complications were defined as moderate and by almost 90% for those with more severe complications. Men who were married were less likely to die than those who were not (risk ratio of 0.75). The risk ratio for non-Caucasians in this study was not elevated above that for Caucasians.

The survival analysis was repeated to include the group of patients who received

no alcoholism-specific treatment. The risk ratios for all variables in the original model were essentially unchanged (data not shown). This group of individuals, however, exhibited a risk ratio of 2.19, relative to those who completed extended formal inpatient treatment, after the other factors in the model were controlled.

Discussion

This study is the largest known effort to examine mortality in alcoholics and one of the first to compare mortality in patients involved in a variety of inpatient treatment options. The large sample size used in this study made it possible to compute age- and race-adjusted mortality rates in the groups studied. These results verify the well-known increase in mortality in alcoholics compared with the general population. The adjusted mortality rate for men completing extended formal inpatient alcoholism treatment was twice that of the general population in 1989.[15] These results are similar to those reported by Schmidt and de Lint[4] and Barr et al.[16] for other groups of treated alcoholics. Neither of these studies, however, was able to capture the increased mortality associated with not completing the full course of inpatient treatment.

Previous work has shown that the risk of death following alcoholism treatment is significantly lower in those individuals who remain abstinent.[16,17] Although we cannot ascertain from our databases which or how many of the men undergoing treatment were successfully able to control their drinking, completing extended formal inpatient treatment was associated with significantly lower mortality compared with persons who received less intense alcoholism-specific treatment. Other researchers have recently found extended inpatient treatment to be associated with better patient outcomes than self-help groups.[18]

Although one would like to ascribe the decreased mortality among those who complete extended formal inpatient treatment to the alcoholism treatment itself, the issue of patients' "self-selecting" to treatment cannot be ignored. However, the incomplete treatment group did provide some control over self-selection.

Other studies of mortality in alcoholics identified through hospital records have grouped those undergoing alcoholism treatment with alcoholics who were hospitalized for other psychiatric and/or medical reasons.[5,6,8,9] This study substantiates the suggestion that these groups are clearly different.[10] Although we have previously shown that the men who received no alcoholism-specific treatment had more severe alcohol-related medical complications,[19] these differences in group characteristics did not completely explain the group's excess mortality. On the other hand, these factors may not be sufficient to explain all of the differences between those who were hospitalized but did not receive directed alcoholism treatment and those who were being treated specifically for alcoholism.

It is possible that patients in the less intense treatment groups received formal alcoholism treatment in years other than the index treatment year. They may also have received treatment from non-VA facilities. Alcoholics who receive VA treatment, however, are largely unemployed, with limited financial resources,[20] and are unlikely to be able to afford inpatient treatment outside the VA. The inclusion of persons who completed additional treatment would have the effect of attenuating the differences between those who completed treatment and the other groups. The reduction in mortality seen in those who completed alcoholism treatment, therefore, would be even more striking.

Taylor and colleagues[6] have suggested that the mortality of female alcoholics is similar to that of their male counterparts. Given the nature of the veteran population, there were too few women alcoholics to include in this study. Thus, we were unable to examine this issue.

Although the prevalence of alcoholism is similar in Caucasian and African-American groups,[21,22] the age-adjusted rate for alcohol-related deaths in non-Caucasian males was much higher than that of Caucasian males for the US population in 1989.[15] Herd also reported higher mortality from cirrhosis among Blacks, particularly in the younger age groups.[23] On the other hand, Mendenhall and colleagues[24] found that survival after diagnosis with alcoholic liver disease in male patients treated at VA medical centers was better for African Americans than for Caucasians, and that other non-Caucasian men fared worse than either of these groups. The higher overall mortality in non-Caucasian males has been attributed to differing racial distributions of socioeconomic status.[25] Because of income eligibility requirements for the use of VA services, these veterans have a relatively uniform lower socioeconomic status. Thus, race in this study may have contributed little excess risk beyond that already accounted for by low socioeconomic status.

It is likely that some alcoholics may have already begun experiencing some of the medical and/or psychiatric complications of alcoholism when they began treatment. Alcoholics with more severe complications may also be high users of both inpatient and outpatient services, suggesting a need to examine the possible relationship between mortality and health care utilization.

The provision of alcoholism treatment has been shown to be beneficial in reducing health care costs.[26] The results of this study, notwithstanding the limitations discussed above, suggest that more intense treatment modalities are also associated with more favorable mortality outcomes. □

Completion Rates of Clients Discharged from Drug and Alcohol Treatment Programs in Washington State

ABSTRACT

Objectives. The primary goal of this study was to analyze completion rates of clients in drug and alcohol abuse treatment programs in Washington State and to assess the factors associated with treatment completion. A secondary goal was to examine the utility of a state information system as a source of evaluative data.

Methods. Analyses were conducted of 5827 client records contained in the Washington State Substance Abuse Monitoring System, representing a census of public clients discharged during the last quarter of 1990 from all state-funded alcohol and drug treatment programs in four treatment modalities. Logistic regression was performed to determine the independent predictors of treatment completion.

Results. Completion rates were highest for intensive inpatient alcohol treatment (75%) and lowest for intensive outpatient drug programs (18%). Factors associated with treatment completion included screening at a referral assessment center, education, age, ethnicity, and existence of a secondary drug problem.

Conclusions. The fit between clients and treatment programs may be an important factor explaining why some clients complete treatment and others drop out. State client information systems are an important source of data for analyzing treatment completion and other outcomes. (*Am J Public Health.* 1994;84: 215–221)

Introduction

Drug abuse and alcoholism represent significant public health problems that have generated increased concern in recent years. In 1989, an estimated $4 billion was spent to support drug and alcohol treatment programs in the United States,[1] almost half of which represented public expenditures. A sizable portion of these expenditures comes from states, which, in the face of federal cutbacks, have had to shoulder a greater burden to support needed treatment programs. Along with this burden has come a greater need for accountability and program monitoring.

These factors have prompted renewed interest in information systems that gather client and program data. Significant resources, at both the federal and state levels, have been devoted to the development of client-based data systems with mixed results. Many systems have had ongoing problems, including reporting delays, incomplete and inaccurate data input, and limited report-generating capabilities. To improve program and client monitoring for drug and alcohol treatment in Washington State, the State Division of Alcohol and Substance Abuse developed the Substance Abuse Monitoring System, a client-based statewide management information system.

In early 1991, the Division of Alcohol and Substance Abuse initiated a project to assess completion rates of state-funded drug and alcohol treatment programs in Washington based on analysis of data from the monitoring system. The project was conducted by researchers at the University of Washington School of Public Health during a 6-month period beginning in April 1991. The purpose of this paper is twofold: (1) to report the results of the analysis and (2) to demonstrate the potential of a state information system to provide data useful for evaluation and analysis. This study is notable because it is based on data representing a large and diverse client population that includes both youth and adult clients, as well as groups for whom treatment completion is rarely analyzed and reported in the literature, including Native Americans, Hispanics, and Asians.

Literature Review

Methodological Problems

Past studies have produced disparate results, probably as a result of differences in subject populations, methods and measures, and definitions of treatment completion. Definitions of completion vary widely. In their landmark paper, Baekeland and Lundwall[2] commented that "definitional inexplicitness has been the hallmark of most studies of dropping out of treatment."

This paper was accepted July 26, 1993.

The lack of conceptual clarity as to who should be categorized as a dropout has fueled inconsistencies. For example, patients who make an appointment but do not keep it are sometimes, but not always, classified as dropouts. Similarly, patients leaving against medical advice but returning later to complete treatment can be classified as dropouts and then new entrants or as completers. Patients asked to leave treatment may be categorized as dropouts or simply excluded from the sample. As a result of these inconsistencies, studies have tended to define program completion in terms of criteria related to length of time in treatment[3] or achievement of treatment plan goals,[4,5] and some studies have simply left treatment completion undefined.[6]

Another problem affecting the reliability of findings reported in the literature is small sample size. Studies based on samples of fewer than 200 subjects,[7–13] or even fewer than 100 subjects[14–17] are not unusual. Even studies with large samples are often limited to a single treatment setting, prompting concern about external validity.[5,18] Many studies exhibit both problems.[19–21] Thus, considerable caution is in order when reviewing findings of studies conducted to assess completion rates.

Factors Associated with Treatment Completion

Dropout rates reported by inpatient drug studies have ranged from 19%[7] to 63%[22]; outpatient drug studies usually report higher dropout rates, with proportions above 70% being the norm.[4,19] Alcohol studies have followed the same pattern, with inpatient dropout rates ranging from 17.4%[18] to 74%[14] and outpatient rates often exceeding 70%.[2,8,15,20]

In general, the drug and alcohol treatment literature has examined the impact on completion of one or more of three characteristics: psychological, demographic, and program related. Psychological studies have found differences between dropouts and completers in terms of several factors, including impulse control, interpersonal difficulties, authority conflicts, motivation to succeed in treatment, and self-concept.[3,6,10,14,21,23,24] However, researchers have questioned the effectiveness of examining psychological factors.[25]

Studies using demographic variables have found that completers tend to be older, married with dependents at home, and wealthier and tend to have health problems related to drinking (such as cirrhosis).[6,14,26,27] Men tend to have higher completion rates than women,[27] but this result is weakened both by the lack of women in most studies[18] and by the greater percentage of men coerced into treatment. Ethnicity has not had a consistent impact, but studies have shown that the ethnic group in the majority within the treatment setting tends to have higher completion rates.[28]

Program variables have also been examined with mixed results. Studies have shown that dropout rates can be reduced by changing the therapeutic atmosphere of the program.[6,29–31] For example, completion rates have been linked to treatment staff vacation schedules[5,32] and to therapy group size.[33] Despite these findings, the long-term impact of program factors on outcomes has been questioned.[11]

Methods

The Substance Abuse Monitoring System database contains detailed information on client characteristics and services provided to individuals whose treatment is supported by state funds. Given the size of this database (upwards of a million records), it was necessary to sample records selectively. The study population was limited to clients discharged during the last quarter of 1990 from the following adult treatment modalities: intensive inpatient treatment, long-term inpatient treatment, intensive outpatient treatment, standard outpatient treatment, and recovery house (a therapeutic setting that provides transitional care for clients moving from inpatient to outpatient treatment). Three types of youth programs were also included: intensive inpatient, intensive outpatient, and standard outpatient. Methadone maintenance and detoxification programs were excluded.

Initial data were obtained on 6682 client records, representing all discharges from the above modalities during the fourth quarter of 1990. These records were loaded into the Rbase database management system and examined for incomplete data as well as out-of-range numeric and alphabetic codes. Of the 6682 records, only 3 had to be discarded because of excessive missing data or nonsensical information. Discharge information indicated that 10 clients had died in treatment and that 110 clients had been inappropriately admitted to treatment. These 120 records were dropped, leaving 6559 records available for analysis. However, 90% (5827) of these records represented discharges in three adult treatment modalities (intensive inpatient, intensive outpatient, and standard outpatient treatment) and one youth treatment modality (standard outpatient treatment). To simplify this study, it was decided to limit the analysis to the 5827 records representing clients discharged from these four modalities.

Program completion status was defined in terms of the discharge categories contained in the system database. These categories included (1) against advice, (2) rule violation, (3) client died, (4) inappropriate admit, (5) other, (6) transfer, (7) default, and (8) completed treatment. All clients with the completed treatment discharge code were defined as program completers. Clients transferred to other programs meeting certain time-in-treatment criteria were also considered to have completed treatment. Clients with the against advice, default, and rule violation discharge codes, as well as transferred clients not meeting the time-in-treatment criteria, were defined as noncompleters.

The judgment of whether a client completed treatment was based primarily on criteria related to length of treatment and secondarily on treatment plan factors. Clients in intensive inpatient programs were expected to remain in treatment from 21 to 28 days. Clients in intensive outpatient programs were expected to stay in treatment at least 1 month but could stay up to 3 months. Furthermore, these clients were to receive counseling and other treatment services at least three times per week for the first month. Standard outpatient treatment usually involved less frequent therapy; the only requirement was that the client be seen once per month unless he or she was under court supervision or some other binding order. No explicitly defined minimum target length of time or maximum time limit was established for standard outpatient treatment. Treatment completion for this modality was defined primarily in terms of progress toward meeting treatment plan objectives.

The Substance Abuse Monitoring System database contains mainly client-related variables. The major variables included in this analysis were age, gender, years of education, ethnic group, usual living arrangement (family vs other), marital status, number of children in household, employment status, referral source (courts, assessment center, other), primary substance abused, income, public assistance status, and existence of a secondary or tertiary substance abuse problem.

Two primary methods of analysis were used to assess program completion rates: cross-tabulation analysis and stepwise logistic regression. Cross-tabulation analysis provided comparative information on program completion rates for client and program variables. Stepwise logistic regression analysis identified variables that were significantly and independently associated with treatment completion ($P < .05$) and provided odds ratios (ORs) and 95% confidence intervals (CIs) for these variables. Separate analyses were conducted for adult drug and adult alcohol treatment programs. Youth programs, which do not distinguish between drug and alcohol clients, were analyzed separately as a single category.

Results

Table 1 presents descriptive data on the characteristics of the adult study population. As shown, the modality with the greatest number of discharges (2082) was standard outpatient alcohol treatment, followed by intensive inpatient alcohol treatment (973). Overall, the three alcohol treatment modalities accounted for almost 70% of discharges of adult clients. Women accounted for approximately 30% of the discharges from alcohol treatment programs and for more than 40% of the discharges from drug treatment programs. Approximately 65% of the adult clients were between 20 and 40 years of age, and more than 70% were White. Blacks represented roughly 15% to 20% of the discharges from drug treatment programs. Native Americans accounted for 16% of the discharges from inpatient alcohol programs and 8% of the discharges from outpatient alcohol programs. Hispanic clients represented a smaller proportion of the study population, roughly 2% to 7% depending on the modality. Most of the adult clients discharged had at least some high school education, and about 15% had attended school beyond this level.

The nature of drug and alcohol problems varied across modalities. A small percentage of clients in adult alcohol programs abused substances other than alcohol, reflecting the mixed nature of addiction developed by some clients (nearly all of these clients had alcohol abuse as a secondary problem). Cocaine abuse was the primary problem for almost half of the clients in adult drug treatment programs, while marijuana abuse was the primary problem for roughly 20% to 25% of the clients. Clients in drug treatment programs appeared to abuse multiple substances more often than clients in alcohol treatment programs. For example, more than 85% of the clients in drug treatment programs had a secondary drug problem, and roughly 55% to 62% had a tertiary drug problem. In contrast, 47% to 66% of alcohol treatment clients had a secondary drug problem, and less than 40% had a tertiary drug problem. As Table 1 shows, clients came into treatment through different avenues. Roughly 90% of the clients in inpatient programs were referred through a central assessment center, while 44% and 62% of the clients entering standard outpatient and intensive outpatient alco-

hol treatment programs, respectively, were referred through the courts.

Table 2 presents descriptive information on the 435 clients discharged from youth outpatient treatment programs during the study period. As shown, 44% of these clients were female, 28% were under 15 years of age, 85% were White, and 76% were attending school. Sixty percent of the youth clients received treatment for alcohol abuse problems; 30% received treatment for marijuana abuse. Sixty-six percent had a secondary drug problem, 26% had a tertiary drug problem, and 23% entered treatment as a result of a court order.

Table 3 presents information on treatment completion for adult clients and shows the results of the cross-tabulation analysis for selected variables. The first noteworthy items are the overall completion rates. As shown, treatment modality was associated with program completion ($P < .001$). Completion rates for intensive inpatient, intensive outpatient, and standard outpatient adult alcohol treatment programs were 75%, 23%, and 40%, respectively. For adult drug treatment programs, completion rates for these same three modalities were 71%, 19%, and 33%, respectively.

Variables found to be associated with completion of adult alcohol or drug treatment programs included age, education, ethnic group, year of addiction, public assistance, and referral source. In general, older clients and clients with more years of education had higher completion rates, but the differences were not always statistically significant. Eighty percent of White clients completed intensive inpatient alcohol treatment; this rate was higher than that for Blacks (71%), Hispanics (73%), and Native Americans (60%). However, the opposite was true for intensive inpatient drug treatment programs, in which 67% of White clients completed treatment as compared with 83% of Black clients, 93% of Hispanic clients, and 77% of Native American clients. Hispanic clients in outpatient drug programs had higher completion rates than clients of other ethnic groups. In almost all cases, clients whose addictions started earlier were more likely to complete treatment.

Finally, completion rates varied by referral source. In particular, adult clients entering treatment through an assessment center that provided centralized diagnostic, treatment planning, and referral services were more likely to complete treatment than clients entering treatment through other avenues, such as court referral. For example, 77% of clients in intensive inpatient alcohol treatment programs referred through an assessment center completed treatment, as compared with 58% of clients referred by the courts ($P = .003$). These results must be considered with some caution, because the many comparisons increase the likelihood of detecting a significant association.

Although analyzed, completion rates for youth clients are not shown in Table 3 to simplify the presentation of results. The overall completion rate for clients discharged from youth outpatient programs was 27%. While there were differences in completion rate among variables, in only one case did these differences achieve statistical significance. Youth clients whose primary drug problem was alcohol or marijuana abuse had higher completion rates than did other clients ($P = .09$).

Finally, stepwise logistic regression was used to identify the variables independently associated with treatment completion (Table 4). The variables most consistently related to treatment completion were age, education, and referral source. Older clients and clients with more years of education were more likely to complete inpatient as well as outpatient treatment. Assessment center screening was a strong independent predictor of treatment completion. Clients discharged from intensive outpatient drug treatment programs screened through an assessment center were almost five times as likely to complete treatment as were other clients.

Ethnicity showed a mixed pattern of relationships. For Native American clients in inpatient alcohol programs, the odds of completion were only about half as great as for other clients. Similarly, White clients were less likely to complete inpatient drug treatment but more likely to complete standard outpatient drug treatment. The odds of Blacks completing intensive outpatient drug treatment were only 15% as great as for other clients. Finally, clients with a secondary drug problem were less likely to complete inpatient alcohol treatment than clients without a secondary problem.

Regression analysis was also performed on data for youth clients. Although not shown in Table 4, two variables were found to be related to the odds of youth clients completing treatment: monthly household income (OR = 1.03 per $100 increase, 95% CI = 1.01, 1.05) and number of children in household (OR = 1.17, 95% CI = 1.03, 1.31).

Discussion

Completion rates were found to be associated with a number of client variables and with treatment modality. The notable finding in regard to treatment modality was the substantially higher completion rates observed for inpatient programs relative to outpatient programs, a finding that has been widely reported* but not well understood. The limited data captured by the Substance Abuse Monitoring System precluded a thorough examination of the many possible reasons for these differences. As Table 1 shows, there were few meaningful differences in client characteristics between the inpatient and outpatient groups studied.

The differences may be related to unmeasured factors associated with programs' therapeutic milieu or treatment setting. Strong clinical norms and peer expectations exist in inpatient substance abuse programs

that may make it more difficult for clients to abandon treatment prior to completion. Also, not completing treatment involves two very different actions depending on whether the individual is an inpatient or outpatient client. A client receiving inpatient treatment must physically leave the treatment setting in order not to complete treatment, while a client receiving outpatient treatment merely has to fail to show up for his or her scheduled therapy.

Unmeasured factors related to source of payment or cost sharing may account for some of the differences in completion rates between the inpatient and outpatient study groups. The treatment of nearly all inpatient clients was supported directly by state funding. However, support for outpatient clients was provided indirectly through the counties, and some income-related copayment may have been required. If so, this requirement may have posed a financial barrier to completion and may explain why fewer outpatient clients completed treatment.

A limited number of variables were found to be significantly predictive of treatment completion in multivariate analyses. In general, older clients, clients with more education, clients with a longer history of substance abuse, and clients referred to treatment through a central referral and assessment center were more

TABLE 4—Stepwise Logistic Regression Models Showing Predictors of Treatment Completion, by Modality

	Adjusted Odds Ratio	95% Confidence Interval	P
Adult alcohol programs			
Intensive inpatient treatment (n = 969)

Years of education	1.09	1.01, 1.18	.041

Note. The following independent variables were included in the logistic regression analysis: age, gender, disability, marital status, employment status, receiving public assistance, eligible for health insurance, White ethnic group, Black ethnic group, Hispanic, Native American, pregnant, Alcohol and Drug Addiction Treatment and Support Act (ADATSA) as funding source, screened by assessment center, fee status, heroin as primary drug, alcohol as primary drug, cocaine as primary drug, marijuana as primary drug, secondary drug use, tertiary drug use, veteran, monthly income, education, number of children in household, first year of addiction, number in household, and living with family. A few records contained missing information and were therefore excluded from the regression analyses. The figures shown represent the numbers of observations used for the regressions.

likely to complete treatment, other things equal.

The findings regarding ethnic group and referral mode merit discussion. Whites were more likely to complete outpatient drug treatment than were members of other ethnic groups, but they were less likely to complete inpatient drug treatment. Native Americans were less likely to complete inpatient alcohol treatment than were clients of other ethnic groups, and Blacks were less likely to complete intensive outpatient drug treatment. These findings may suggest the importance of cultural fit between clients and treatment programs.[28] Ethnicity per se may not be as important as the fit between one's ethnic group and the norms and culture of the program.

This notion of client–program fit may extend to other areas as well, particularly the fit between the client's substance abuse problem and the treatment focus. The regression analysis indicated that clients in intensive inpatient alcohol programs whose primary problem involved abuse of a substance other than alcohol were only about half as likely to complete treatment as were clients whose primary problem involved alcohol abuse.

The fit between client and program has important clinical implications and may explain why referral mode, particularly referral through a centralized assessment center, was found to be an important independent predictor of treatment completion. Assessment centers provide centralized intake, screening, and referral of clients, which may lead to a better fit between the program and client than would otherwise occur, for example, when clients are referred to treatment through the courts.

How do these results compare with other findings reported in the literature? While comparisons must be made cautiously, it appears that the completion rates described here are somewhat higher than those reported by other studies.[2,14,18,31]

One important limitation of the present study was its focus on a single treatment episode. Clients with substance abuse problems often move in and out of treatment over time. What may be important for achieving abstinence or positive outcomes (e.g., employment) in the long run is the cumulative effect of multiple treatments over time rather than the fact of treatment completion for a single treatment episode. The results of the regression analysis indicated that clients with fewer years of addiction were less likely to complete intensive outpatient drug and alcohol treatment than were clients with a longer history of addiction. The latter clients probably had greater exposure to treatment over time, and the cumulative effects of this previous treatment may have increased the likelihood of their completing the current treatment episode. Unfortunately, it was not feasible within the scope of this study to extract data from the Substance Abuse Monitoring System that would have allowed us to link records over time to construct a variable that could reliably measure past treatment.

Treatment completion is believed to be important because it presumably has a positive effect on long-term outcomes. It was not feasible, in the present study, to perform long-term follow-up on clients. Thus, we do not know whether the clients in this study who completed treatment had better long-term outcomes than those who did not complete treatment.

In addition to analyzing treatment completion, this study had a secondary purpose: to demonstrate the potential of a statewide information system to provide reliable data for analysis. Only 3 of the more than 6000 records we obtained for the project proved unusable as a result of poor data, a remarkable fact. Furthermore, an independent study of youth treatment programs, undertaken at the same time as our study and involving actual reviews of client files, generated completion-rate estimates virtually identical to those reported here.

Our experience suggests that state information systems can provide a rich

source of data, yielding information that is sufficiently complete and timely to provide a basis for meaningful analysis. Yet the capabilities of many state systems appear to be rather limited.[34] A critical need for improving understanding of treatment effectiveness through analysis of information contained in state information systems is the ability to track clients over time and to link treatment episodes. Building the capacity to do so, even on random samples of clients, would greatly enhance the capability of these information systems to provide meaningful data.

From a health policy perspective, the question of the effectiveness of substance abuse treatment has taken on added importance in the context of health care reform with discussion of expanding health insurance coverage for mental health and substance abuse treatment. On the private side, the cost of substance abuse treatment has risen dramatically in recent years and is now one of the fastest growing expenditure categories, a fact that has prompted employers and insurers to scrutinize treatment much more closely and to question its value. The need for information systems that can provide reliable data to support and enhance planning and evaluation of substance abuse treatment services will doubtlessly grow in the future.

Further study will be needed to better understand the factors predictive of program completion. This study suggested the notion that fit between the client and program may be a key factor explaining why some clients complete treatment and others drop out. In this regard, there is a need for careful systematic assessment of how different referral mechanisms may influence client–program fit. More generally, there is a need to better understand how program factors, which may be amenable to change through health policy or management initiatives, may affect completion rates as well as long-term outcomes. □

Ethnicity and the Use of Outpatient Mental Health Services in a National Insured Population

Deborah K. Padgett, PhD, Cathleen Patrick, PhD, Barbara J. Burns, PhD, and Herbert J. Schlesinger, PhD

ABSTRACT

Objectives. Factors affecting ethnic differences in the use of outpatient mental health services are analyzed in an insured, nonpoor population to determine if lower use by Blacks and Hispanics persists when socioeconomic and other factors are controlled.

Methods. To identify significant predictors of the probability and amount of use, insurance claims data for a population of 1.2 million federal employees insured by Blue Cross/Blue Shield in 1983 were analyzed with the Andersen and Newman model of health service utilization. Logistic and ordinary least squares regression models were estimated for each ethnic group.

Results. Blacks and Hispanics had lower probabilities and amounts of use when compared with Whites after controlling for a number of variables.

Conclusions. Since ethnic differences in the use of outpatient mental health services exist even in an insured, nonpoor population, factors other than lower socioeconomic status or insurance coverage—for example, cultural or attitudinal factors and service system barriers—are likely responsible. Such findings have policy implications in the current climate of health care reform to increase access to care for the underserved. (*Am J Public Health.* 1994;84: 222–226)

Introduction

National priorities supporting mental health research on ethnic minorities were set forth in the 1978 report of the President's Commission on Mental Health.[1] However, most studies of ethnic use of mental health services have been confined to public sector institutions such as state and federal psychiatric hospitals and community mental health clinics; use of private sector mental health services is rarely captured.

While information on all forms of mental health services use by ethnic groups is critical to establishing sound policies in financing and services delivery, relatively little is known about how members of ethnic groups use outpatient mental health services, especially when comprehensive insurance coverage is available to them. A review of the literature on ethnicity and the use of outpatient mental health services reveals two consistent patterns. First, all ethnic/racial groups (including Whites) underuse mental health services relative to need, as indicated by the Epidemiologic Catchment Area studies sponsored by the National Institute of Mental Health in the early 1980s,[2–6] which were instrumental in documenting gaps between need for and use of mental health services in the general US population.[3,5,6] Second, findings from these and other studies have consistently shown that the gap between need and use is greatest for members of ethnic minority groups.[7–11] Thus, rates of outpatient mental health services use tend to be lower among Blacks and Hispanics than among Whites.

Ethnic differences in the amount of mental health services used have also been noted, although findings are not always consistent. While Blacks, Asian Americans, and Hispanics generally make fewer outpatient visits than Whites,[8,12–15] Wells et al.[10] and Hu et al.[16] report no significant ethnic differences in the amount of use once treatment has begun.

Some researchers have noted that interethnic differences in mental health services use are the result of socioeconomic differences and are minimized when these factors are controlled.[10,15,17] However, little is known about how factors such as insurance coverage and service availability affect the likelihood of seeking outpatient mental health treatment among different ethnic groups and to what extent the influence of such factors differs across ethnic groups.

The first goal of this study is to assess factors influencing the use of outpatient mental health services among ethnic groups in an insured, nonpoor population. Our database of more than 1.2 million federal employees and their family members insured by Blue Cross/Blue Shield in 1983 offered a rare opportunity to examine and compare service use by Whites, Blacks, and Hispanics in a large national population.

The second goal is to discuss the policy implications of this study's findings with regard to the financing and delivery of mental health services to ethnic minority groups in the 1990s. The past decade has brought enormous increases in health

care costs along with renewed calls for national health insurance.[18] We argue that this study's findings can provide insight into ethnic patterns of use under a system of national health insurance.

Methods

Database

The study used insurance claims and related enrollment data from federal employees and their family members who were insured by the Blue Cross and Blue Shield Association's Federal Employees Plan in 1983. For outpatient mental health care, the high-option plan copayment was 30% with a $200 deductible and a 50-visit maximum, and the low-option plan copayment was 25% with a $250 deductible and a 25-visit maximum. The deductible included all medical claims, not just those for mental health treatment. It is likely that usage below the deductible is included in these data since Blue Cross/Blue Shield encouraged enrollees to file claims even when those claims did not exceed the deductible.

The study sample comprised all persons who had at least one outpatient mental health visit in 1983 and random samples of approximately 5000 nonusers selected within each ethnic group. In subsequent analyses, these samples were weighted to estimate the total number of persons who did not have outpatient mental health treatment. The preexisting structure of the database required that only families enrolled for 5 or more years were included.

Predictors of Probability and Amount of Use

Following the Andersen and Newman model of health service use,[19] three sets of independent variables were developed: predisposing, enabling, and need factors. Most of the predisposing variables are self-explanatory (e.g., age, sex, etc.). However, the rationale for using the percentage of the county that was Black, Hispanic, or White as a measure of ethnic congruity was as follows: Tweed et al.[20] found that persons residing in areas characterized by the numerical dominance of own-group members manifested lower levels of psychological distress when compared with persons living in racially "dissonant" areas. We reasoned that the level of ethnic congruence in a person's geographic area might also influence that person's decision to seek mental health care.

Overall	100.00	2.26	9.7	100.00	2.77	8.6	100.00	3.66	13.0

Enabling factors included region, salary of the employee, and high- or low-option plan. Region of country was considered an enabling factor since the availability of mental health services varies considerably.[21] For analyses predicting the number of visits, the setting of the first visit and the type of mental health practitioners sought were included. As classified in the claims data, such practitioners included physicians, psychologists, and mental health workers who were clinical social workers and psychiatric nurses. Physician specialty was not available from the Federal Employees Plan data and may have included either psychiatrists or general practitioners. Two enabling variables from the Bureau of Health Professions Area Resource File provided county-level measures of the relative availability of outpatient mental health services: the percentage that was urban and the ratio of psychiatrists to physicians.

Although specific mental diagnoses were unavailable, several variables were useful as indices of need for mental health treatment: the individual's and the rest of the family's annual medical expenses, prior inpatient psychiatric treatment during the year by anyone else in the family, and the total number of mental health visits made by all other family members. For the amount-of-use analyses, whether the individual also had inpatient mental health treatment during the year was included as a dichotomous yes/no variable. (In analyses predicting any use of outpatient mental health services, the term "individual" refers to any member of the study population; in analyses predicting the amount of use, it refers to the user of outpatient mental health services.)

Dependent Variables

Following previous analyses of mental health services use,[22–24] probability of use and amount of use constituted the two dependent variables. The first was coded "1" if the individual had a visit claim coded "nervous and mental" during the year, and "0" otherwise. The second variable was the number of mental health visits made during the year given any use.

Data Analysis

Weighted logistic regression models were developed separately for each ethnic group to calculate odds ratios (ORs) and 95% confidence intervals (CIs) to predict the probability of use. For predicting the amount of use, ordinary least squares regression was used. Variables were en-

[c]Odds ratios for the continuous variables used in the model and their corresponding unit increases are as follows: (1) salary in units of $10 000, (2) psychiatrist to physician ratio in units of 0.1, (3) total medical charges for the sampled individual and for the rest of the family in units of $1000, (4) outpatient mental health visits for others in the family in units of five visits.
*Variables were statistically significant at $P = .05$.

tered into the regression equation following hierarchical procedures recommended by Cohen and Cohen.[25]

Results

Characteristics of the Population

Men made up a slightly greater proportion of Whites and Hispanics than of Blacks (see Table 1). There were noticeable differences in regional distributions for the three groups. It is difficult to explain why three fourths of Blacks and Hispanics chose the high-option plan while only 58% of Whites chose this plan. Federal employee education was substantially higher for Whites.

Outpatient Mental Health Services Use

As shown in Table 1, Blacks had the lowest rate of outpatient mental health services use, followed by Hispanics and then Whites. Sociodemographic breakdowns resulted in similar patterns across the groups, with women, 18- to 45-year-olds, high-option enrollees, and the more educated having higher rates. For Whites and Hispanics, the highest rate of use was in the Washington, DC, area; for blacks, it was in the western states.

Hispanics averaged the fewest number of visits, followed by Blacks and then Whites (see Table 1). While there were few gender differences, 18- to 45-year-olds, those living in the Washington, DC, area and in the Northeast, the more educated, and high-option enrollees averaged more visits.

Predicting the Probability of a Mental Health Visit

Table 2 shows that, for each group, being aged 18 to 45 as compared with being older was statistically significant (for Blacks: OR = 1.40; CI = 1.19, 1.64; for Hispanics: OR = 1.19; CI = 1.00, 1.42; for Whites: OR = 1.43; CI = 1.30, 1.57), as were the number of mental health visits made by other family members (for Blacks: OR = 1.30; CI = 1.17, 1.44; for Hispanics: OR = 1.37; CI = 1.22, 1.53; for Whites: OR = 1.27; CI = 1.21, 1.33). For Blacks, the only other significant predictor was education (OR = 1.07; CI = 1.00, 1.14). Education was also a significant predictor for Whites (OR = 1.11; CI = 1.07, 1.14) but not for Hispanics (OR = 1.05; CI = 1.00, 1.11).

Additional significant predictors for Hispanics were being over age 46 compared with being under age 18, having a high-option plan, and having higher medical costs for the individual. For Whites, these same variables were significant, with the addition of female gender, living in the District of Columbia area compared with living in the north central or southern states (odds ratios less than 1 require reversing the coding for these variables), and percentage urban population in the county of residence.

Predicting the Number of Mental Health Visits

Results in Table 3 reveal that, while many of the significant variables are predictably associated with higher levels of use, other predictors are lesser known. For example, ethnic congruence was significant for all three groups, although not in the same direction: it was positively associated with the number of visits for Blacks, but it was negatively associated for Hispanics and Whites.

Provider type and setting were also significant for all groups, with more visits associated with visiting an office (vs a clinic or hospital) and with visiting a psychologist (vs a physician). Medical costs of the individual and of others in the family were generally inversely related to the number of visits. Use of inpatient mental health services was positively and significantly related to the amount of outpatient use for Hispanics and Whites but not for Blacks.

Do Ethnic Groups Differ after Adjustment for All Covariates?

In a test of the overall hypothesis of whether statistically significant ethnic group differences remained after adjusting for all covariates in the study (comparing all three groups simultaneously), Whites had 1.7 times greater odds of making a visit compared with Blacks and Hispanics ($P < .004$). There was no significant difference between Black and Hispanic odds of making a visit. In the ordinary least squares regression model, Whites were

estimated to make 2.64 more mental health visits during the year than Hispanics and Blacks ($P < .001$). There was no significant difference found between Hispanic and Black users.

Discussion

This study has demonstrated that ethnic differences in the use of outpatient mental health services persist even in an insured population after a number of potentially confounding factors are controlled. The significance of enrollment in the high-option plan for Hispanics and Whites (but not for Blacks) is an indication that use of outpatient mental health services is responsive to insurance coverage in these groups. Although it is difficult to explain why plan option is not significant for Blacks in predicting the probability of use, it is easier to see how more generous coverage is significant for all groups in predicting higher amounts of use for those persons in treatment.

We also note that significantly higher levels of use are associated for all three groups with visiting an office-based practitioner and with visiting a psychologist. This effect of visiting a psychologist was also reported by Taube et al.[24]

While few of the indices of need proved to be influential, use of outpatient mental health services by other members of the family and higher medical costs of the individual were significant. These variables might be seen as indicating the influence of stress within the family and of physical comorbidity for the person seeking mental health treatment.

The cumulative results of this and previous studies point to a clear pattern of lower use by Blacks and Hispanics compared with Whites. While this phenomenon is more noticeable among the ethnic minority poor,[26] it is discernible even in this study's nonpoor population for whom many socioeconomic and other differences are minimized or controlled. We also note that the influence of differential acculturation is minimized in this population since unacculturated and/or non-English-speaking persons are unlikely to be included.

The reader is cautioned that these analyses captured usage during a 1-year period. Persons who used outpatient mental health services may have begun treatment prior to January 1, 1983, or continued treatment after the end of the year. Thus, our database restricted our analyses to annual usage rather than to episodes of treatment. We also acknowledge that the absence of diagnostic data limited our understanding of the nature and severity of the mental problems. However, some researchers have argued that diagnostic data may be more suspect in cross-ethnic comparisons.[27] Insurance claims data do have an advantage over self-reported data in studies of ethnic groups, in which underreporting of embarrassing or socially stigmatizing events such as visiting a mental health specialist has been noted.[27]

Given the enormous changes that have taken place in the delivery of mental health services since the early 1980s, this study's findings may at first glance appear to be of more historical value than current interest. Interestingly, there are no available sources of national data of more recent vintage. The most recent study allowing national estimates of rates and amounts of use—the National Medical Expenditure Survey—took place in 1987, but usage data were not yet available as of this writing.

However, we would argue that this study's findings are applicable to the current and future situation in the United States. Concerns about spiraling health care costs and the rapidly growing number of uninsured persons have led to renewed calls for national health insurance,[18,28] and several of the comprehensive proposals resemble the Federal Employee Plan's benefit structure.[18] Under national health insurance, low-income Blacks and Hispanics may gain the same coverage and access to mental health care as their employed counterparts had in the federal plan. As noted by Weil,[18] studies using resources such as the federal plan's database might provide

[c]Regression weights for the continuous variables used in the model and their corresponding unit increases are as follows: (1) salary in units of $10 000, (2) psychiatrist to physician ratio in units of 0.1, (3) total medical charges for the sampled individual and for the rest of the family in units of $1000, (4) outpatient mental health visits for others in the family in units of five visits.
*Variables were statistically significant at $P = .05$.
**Variables were statistically significant at $P = .01$.

insight into how various ethnic groups use mental health services under a national plan. We acknowledge that Whites, Blacks, and Hispanics in the Federal Employee Plan population are not fully representative of their uninsured counterparts in the general US population, where the prevalence of severe mental disorders is reported to be higher[4]; differences in usage may be expected owing to a greater need associated with the lower socioeconomic status experienced by ethnic minorities. However, this study's primary finding that Whites use more mental health services even in an insured population points to the possibility that ethnic differences may persist even under national health insurance.

Clearly, the use of outpatient mental health services is governed by a number of factors related to the individual and the service delivery system. Many researchers suggest that cultural or attitudinal factors play a strong role in lower use by Blacks and Hispanics.[9,10,26,29,30] Such factors can take many forms, from reluctance to use a health delivery system dominated by English-speaking Whites to preference for alternative healers or clergy more attuned to the culture of the individual. We recommend that future research examine perceptions of barriers as well as use of alternative healers. A more balanced and complete picture would also include attention to protective factors and coping resources related to ethnic identity[31] rather than an exclusive focus on individual psychopathology.

Aspects of the service delivery system play a role as well. The absence of ethnic mental health practitioners is one of the most conspicuous barriers. Also, the intersection of lower social class status and ethnicity, combined with residential segregation, leads to inequities in service delivery that disproportionately affect Blacks and Hispanics. An inner-city resident who has insurance coverage will have more difficulty finding a clinic or mental health practitioner than will a resident of an affluent neighborhood. Finally, an ignorance of the more subtle aspects of cultural and social class differences may contribute to an appearance of insensitivity and thus inhibit the pursuit of care. Qualitative studies are needed to examine the process of mutual estrangement that can result from cultural misunderstandings.

As implied by this study, increasing equity and access under national health insurance will not necessarily close the gap in ethnic use of mental health services. Whether this gap is due to lower availability of services, lower acceptability of services, or both, points to an intriguing point of departure for future research and for planning mental health policies that are effective as well as humane. □

Mental Health Status as a Predictor of Morbidity and Mortality: A 15-Year Follow-Up of Members of a Health Maintenance Organization

Thomas Vogt, MD, MPH, Clyde Pope, PhD, John Mullooly, PhD, and Jack Hollis, PhD

ABSTRACT

Objectives. This study sought to relate preexisting depression, worries, affect balance, and mental health symptoms to subsequent risk of morbidity and mortality.

Methods. A random sample of members of a health maintenance organization were interviewed at home in a 1970/71 survey. Baseline psychological measures from that survey were then related to 15-year mortality and first incidence of cancer, heart disease, hypertension, stroke, functional gastrointestinal disease, and hyperimmune diseases.

Results. Baseline depression and the Langner Mental Health Index predicted incidence of functional gastrointestinal and hyperimmune diseases. The relationship of the Langner index to hyperimmune diseases was particularly strong; mortality, cancer, heart disease, hypertension, and stroke incidence were not related to that index. Except for affect balance, which was worst in the elderly, indications of psychological dysfunction were strongest in the young.

Conclusions. Psychological indices detected increased risk for functional gastrointestinal and hyperimmune diseases but were not related to mortality risk. Further research is needed to disaggregate relationships of the specific conditions that were included in the hyperimmune group. Functional gastrointestinal disease might be preventable with early attention to depressed persons and to those scoring high on the Langner index. (*Am J Public Health.* 1994;84: 227–231)

Introduction

An extensive literature examines the relationship of psychological distress to mortality risk.[1-11] In presenting their own negative data, Roberts et al.[4] surmised that reported associations of psychological state to mortality are misleading because case–control and cross-sectional studies have generally involved persons who are psychologically impaired and thus are not representative of the broader population. Community studies, on the other hand, have been less likely to make such associations.[4-14] Animal studies demonstrate clear relationships between various stresses and immune response, both in vitro and in vivo[15,16]; such effects, if they persist over long periods, might be expected to influence susceptibility to selected morbidities. A meta-analysis of the role of personality in disease causation[17] suggests the possible existence of a "disease-prone" personality that is characterized by anger/hostility and anxiety.

This paper examines the extent to which four baseline measures of mental and emotional health and well-being were able to predict 15-year morbidity and mortality in a random sample of adult enrollees in a large health maintenance organization (HMO). The four measures examined were the Langner Mental Health Index, a depression scale, the Bradburn-Caplowitz Affect-Balance Scale, and the Bradburn Worries Index. The relation of morbidity and mortality in this group to social networks has been examined separately.[18]

Methods

Study Population

The study population was a random sample of 1659 household units with 2573 adult members of the Northwest Region of Kaiser Permanente, a large managed-care organization in Portland, Ore, whose membership is generally representative of the Portland, Ore/Vancouver, Wash, standard statistical metropolitan area.[19] Subjects were respondents to a 1970/71 personal interview survey. Of the households randomly selected, 92% (1529) were successfully interviewed. Thirty individuals who left the health plan less than 6 months after the survey interview were eliminated from the analyses. To be eligible, individuals had to have been enrolled in the health plan prior to January 1, 1969, thus permitting 2 years of retrospective medical records review prior to the survey. Medical records for this population were routinely abstracted from the date of enrollment or January 1967, whichever was earlier.

Independent Variables

The baseline measures were derived from the 1970/71 personal interview survey. These measures include self-reported general health status and scores on the Langner Mental Health Index, a depression scale, the Bradburn-Caplowitz Affect-Balance Scale, and the Bradburn Worries Index.

The Langner index[20] is a count of the number of 22 symptoms (e.g., headaches, night sweats, heart pounding, trouble sleeping, etc.) the respondent often experiences. It is scored from 0 to 22 (mean = 2.19, SD = 2.38). Although de-

signed as a general measure of mental health, it is widely regarded as an index of psychophysiological symptomatology and general malaise.[21]

The depression index was created from questions on the survey that allowed a close approximation of the clinical definition of depression in the American Psychiatric Association's *Diagnostic and Statistical Manual*, 3rd edition.[22] The instrument and distributions of scores on its component questions are discussed in McFarland et al.[23]

The Bradburn-Caplowitz Affect-Balance Scale[24] was created from questions asking about five negative and five positive emotional states (e.g., during the past few weeks, did you ever feel proud? lonely?). To an initial score of 5, +1 is added for each "yes" response to a positive emotional state and −1 for each "yes" response to a negative emotional state. Scores range from 0 to 10, a higher score indicating a positive affect (mean = 7.22, SD = 1.79).

The Bradburn Worries Scale[25] consists of 12 items (e.g., during the past few weeks, have you been worried about money? job? world?) weighted from not worried (0) to very worried (2). Scores range from 0 to 24 (mean = 3.48, SD = 2.66). This index is intended to reflect transitory mental states (unlike the Langner index, which purportedly measures more enduring states).

Dependent Variables

Vital status as of the end of 1985 was determined for all members of the study population through searches of the national death index and vital records for Oregon and Washington states.

International Classification of Diseases, version 7 (ICD-7)[26] codes were used to classify all confirmed morbidities for all years of the study. The use of a single coding system prevented discontinuities secondary to ICD code revisions.

The first incidence was determined for the following morbid outcome groups (ICD-7 codes): ischemic heart disease (420, 421.5, 422.1), cancer (140–205, excluding 191), stroke (330–334, 335.1), hypertension (447.0, 447.2), infection (002–138), diseases of hyperimmunity (allergy [240, 242–245], asthma [241], osteoarthritis [723], autoimmune diseases [252.0, 254.0, 256, 271.1, 290.0, 296, 456, 704, 744]), and functional gastrointestinal diseases (540–544, 571–573). Persons with a past history of a morbid condition were excluded from analyses of that condition so that the outcome was always defined as the first incidence of a morbidity.

Analyses

Cox proportional hazards regression models were used to assess the 15-year relative hazards of mortality and morbidity. These nonparametric models allow the hazards of death and disease incidence to include follow-up time but require that the proportional effects of predictors on hazards be constant over the entire follow-up interval. The Cox regression procedure allows censoring due to health plan disenrollment and includes a goodness-of-fit test of the proportional hazards assumption. The exponential function of a Cox regression coefficient is the relative hazard of the outcome for a unit difference in the predictor variable.

Analyses were adjusted for age, sex, self-reported health status, self-reported social class, cigarette smoking status, and duration of health plan membership. For most of the analyses, the predictor variables were divided into approximate tertiles, with the upper (high) tertile serving as the referent for comparisons with the bottom (low) tertile. The SAS SUGI procedure PHGLM[27] was used.

Kaplan Meier and log-log hazard plots and proportional hazard z scores were used to verify Cox model assumptions. Stepwise inclusion criteria were used to identify interactions of age, gender, and baseline subjective health status that significantly improved the predictive power of the main effects models.

Results

Table 1 shows the characteristics of the study population. The population is a broadly distributed group of HMO members generally representative of the metropolitan area from which they were drawn.

Table 2 presents the percentage of individuals within each of five age groups that fell into the approximate tertiles of the various psychosocial measures. For each measure, cut points were selected that most nearly distributed the respondents into thirds. Depression scores were highest in those under 30, followed by those over 75. Those from 30 to 74 years of age were least likely to be depressed. Persons under 30 were least likely to fall in the lowest (most healthy) tertile on the Langner scale and most likely to fall in the highest tertile. Persons aged 60 to 74 were most likely to fall in the lowest tertile. The worries index was inversely related to age, with the two oldest age groups (60 and above) showing the fewest worries. Persons over age 75 were most likely to fall in the lowest tertile of affect balance (worst affect balance), and those aged 30 to 44 had the highest affect-balance.

Table 3 presents the Pearson correlations among the four psychological scales. Depression and the Langner index were highly correlated (r = .83). The other measures were significantly but more weakly correlated.

Table 4 presents the 15-year relative hazards (RHs) of mortality and morbidity incidence. For each index, the lowest tertile was compared with the highest tertile. The table includes both unadjusted rates and rates adjusted for age, sex, smoking status, socioeconomic status (SES), self-reported health status, and duration of health plan membership.

Those in the low and medium tertiles of the depression index at baseline (not depressed) were at increased risk for subsequent hypertension compared with those scoring high on the depression index. Depression was also related to an increased incidence of functional gastrointestinal disease and was marginally as-

sociated with an increased hazard for diseases of hyperimmunity. The other five dependent variables were not related to depression. For men only (data not shown), the risk of dying during the follow-up interval was lower for the least depressed compared with the most depressed tertiles (RH = 0.71; confidence interval [CI] = 0.52, 0.97). No other interactions with sex were observed.

A high score on the Langner index was related to an increased risk of both functional gastrointestinal and hyperimmune diseases among all persons. The index interacted with age in predicting incidence of hypertension. Younger individuals with a low mental health score were at increased risk for hypertension (RH = 1.47; CI = 1.05, 2.04 at age 30), while older persons with a low mental health score were at reduced hazard (RH = 0.76; CI = 0.62, 0.92). No other main effects or interactions were noted.

A high score on the worries index was associated with an increased risk for functional gastrointestinal disease. The worries index was also strongly related to mortality and to incidence of ischemic heart disease, cancer, hypertension, and stroke in the unadjusted analyses. Adjustment for age, sex, smoking, health status, SES, and duration of health plan membership abolished these relationships.

The unadjusted affect balance score was significantly associated with mortality, ischemic heart disease, stroke, and functional gastrointestinal disease. After adjustment, the affect balance scale was not significantly associated with any of these outcomes, but low affect balance was marginally related to elevated risks of death and stroke.

To assess the degree to which the addition of the mental health variables improved the fit of a model involving only covariates, we reran all the models without the mental health variables (i.e., with covariates only). We then used the likelihood ratio test to determine whether the main effects models of covariates alone were significantly improved by the addition of the four mental health indices. Addition of the depression, Langner mental health, and worries indices to the model produced highly significant improvements in the model for all outcomes except in the case of the worries index as a predictor of stroke. *P* values associated with these chi-squares were extremely small—in most instances, much less than .0001. The affect balance scale was not associated with a significant improvement in the model for any of the outcomes except cancer incidence ($P < .005$).

TABLE 2—Percentage of Participants, Distributed by Age, within Tertiles of Psychological Scales

Discussion

These analyses show a strong prospective association between the mental health, depression, and the worries indices, on the one hand, and the first incidence of functional gastrointestinal disease and a group of diseases we classified as diseases of hyperimmunity, on the other. Unfortunately, this latter grouping was created for other reasons, and we were not able to break up that group into its major component parts (allergies/hay fever, asthma, osteoarthritis, autoimmune diseases). We plan to do so in the future. In the adjusted models, psychological indices were not related to mortality hazard (except possibly for depression among men only) or to the incidence of major morbidities such as ischemic heart disease and cancer. The unadjusted worries and affect balance indices were strongly related to these outcomes, however, emphasizing the importance of appropriate adjustments when analyzing the relationships of psychological variables to morbidity and mortality.

The relationship of three of the four indices to functional gastrointestinal and hyperimmune conditions is intriguing. Functional gastrointestinal diseases obviously have a strong psychological component. But, to our knowledge, this is the first evidence that a depression index, the Langner Mental Health Index, and the Bradburn Worries Scale can be used to identify those at high risk for future functional gastrointestinal disease. A 1957 study of army recruits[28] probably gave rise to the general perception that personality and ulcer are linked, but no well-controlled studies exist that confirm this commonly held perception. Similarly, arthritis, particularly rheumatoid arthritis, is often perceived to be related to psychological factors. Persons with rheumatoid arthritis have more psychological problems than controls and appear to have more psychological stress.[29] Certainly, rheumatoid arthritis is involved with immune response. But prospective studies

[a]Low tertile relative to high tertile; adjusted for age, sex, socioeconomic status, length of health plan membership, subjective health status, and smoking.

on these issues are woefully lacking. Is it possible to intervene with appropriate therapy for those who score high on these indices and thereby to reduce future functional gastrointestinal conditions and/or conditions associated with excessive inflammatory/immune response? This question deserves further attention.

There are well-described biochemical pathways that might link hypothalamic-adrenocortical hormones to the risk of heart disease and cancer.[30,31] Despite the common, yet relatively undocumented, knowledge that periods of stress are related to exacerbations of asthma, allergies, and arthritis, there is no comparable biological model to account for the relationships between psychological factors and excessive immune response. There have been observations that persons with allergies are at decreased risk for cancer,[32] but little has been done to specify whether (or how) psychological states might be involved. The present study suggests that perhaps these morbidities are linked to psychological states. This study has also examined the relationships of social networks[18] and other psychosocial variables to these outcomes.

Although the depression and mental health indices are highly correlated, only the former was inversely related to the risk of newly diagnosed hypertension. Physicians may be less likely to diagnose asymptomatic conditions such as hypertension in depressed patients than in nondepressed patients, and/or depression may be associated with reductions in blood pressure. There is no basis for attributing this inverse relationship to antidepressant medications. Such medication might, in fact, be expected to increase blood pressure.

Although affect balance, a measure of well-being, tended to be negatively related to the risk of death and stroke, it was not significantly associated with any of the study outcomes after adjustment for covariates.

Persons under 30 years of age were more depressed and more worried and had more long-term mental health symptoms than other age groups. Only affect-balance was worse among the old than the young. The high completion rate (92%) of the random sample suggests that these findings are not the result of a healthy volunteer effect and that age does not lead to a general deterioration in these aspects of mental health. Indeed, some aspects appear to improve with age.

Of course, many comparisons were performed in conducting these exploratory analyses, and some significant associations might be expected by chance alone. However, the associations reported here are very powerful, and few are likely to have resulted from chance. It is possible that specific morbid conditions present at baseline may have confounded the observed relationships. Further exploration of the relationships of these mental health indices to morbid conditions would help to detect such problems.

Further exploration of the relationships between psychological states and the future risk of functional gastrointestinal and hyperimmune conditions is warranted. In particular, the relationship of these measures to the subcomponent conditions that make up the hyperimmune group would be of interest. □

Dementia-Free Life Expectancy in France

Karen Ritchie, PhD, Jean-Marie Robine, PhD, Luc Letenneur, PhD, and Jean-François Dartigues, PhD

ABSTRACT

Objectives. Increasing concern with the quality of gains in life years has led to the development of a new synthetic indicator of population health:health expectancy. Until now, calculations have been made for physical disabilities only. A first estimate of mental health expectancy is presented: dementia-free life expectancy.

Methods. Sullivan's method was used to calculate dementia-free life expectancy for a random representative sample of 4134 persons over 65 years of age in the Bordeaux region of France. The diagnosis of senile dementia was made in two stages, based on *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) criteria.

Results. At 65 years of age, a person's dementia-free life expectancy is 16.9 years within a total life-expectancy of 17.7 years; it decreases with age in parallel with the decrease in total life expectancy so that life expectancy with dementia stays constant at 0.8 years. Although dementia prevalence increases with age, if the prevalence is adjusted for mortality, the largest number of persons with dementia are in their early eighties. At each age women have a higher dementia-free life expectancy.

Conclusions. Trends in dementia-free life expectancy are similar to those found in disability-free life expectancy. Because the dementia prevalence rates used in this estimate resemble a general model derived from meta-analysis, it can be assumed that similar results will be found in other Western countries with similar mortality rates. (*Am J Public Health.* 1994;84:232–236)

Introduction

Perhaps one of the most striking recent changes in the field of public health has been the appreciation that health is more than survival and that health care policy should look beyond extending life to assess the impact of disease both on the individual's capacity to lead a normal life and on the society that cares for the individual. This change in emphasis, in conjunction with the observation that increases in life expectancy appear to be accompanied by increases in the prevalence of chronic disease and disability, has led to widespread interest in the concept and calculation of "healthy life expectancy." Studies of health expectancy examine changes in mortality in relation to the prevalence of physical disease and disability, thus addressing the question of whether the years we have gained as a result of preventive and therapeutic health programs are years of good or poor health.

A large number of health expectancy calculations have now been made in both developed and developing countries[1,2]; however, these have all focused on the measurement of physical disability. Mental disorder has received little attention, although a strong motivating force for calculations of health expectancy has been the theory of Kramer, who predicted in 1980 a "coming pandemic of mental disorders and associated chronic diseases and disabilities."[3] Kramer's work, which is principally based on the results of population studies of senile dementia and schizophrenia, clearly targets mental disorder as the primary area of concern. Although the entire range of mental disorders has yet to be explored in the context of health expectancy calculations, life expectancy free of senile dementia (referred to here as dementia-free life expectancy) is perhaps the most urgent, as the prevalence of dementia increases with age[4] and considerable concern has been expressed by health professionals that increased life expectancy, particularly among the oldest of the old, will lead to an epidemic of senile dementia by the end of the century.

In France as in other Western countries, approximately 50% of long-stay hospital beds are presently occupied by elderly persons with senile dementia. This condition involves progressive and irreversible deterioration of all cognitive functions, with rapid loss of autonomy and independence. The burden for both professional and family caregivers is considerable: the average length of survival from dementia onset is 8 years,[5] no specific medical treatment is presently available, and persons with dementia have increased susceptibility to a wide range of physical disorders.[6] Progressive loss of language accompanied by failure to recognize family and friends lead to rapid social exclusion. If the aim of health expectancy calculations is to determine the quality of gains in life expectancy, then age-related intellectual deterioration cannot be overlooked; it will affect not only the elderly person but also the person's caregivers, who themselves will be at increased risk of both physical and mental ill health.[7]

This paper was accepted June 23, 1993.

Given that functional loss is one of the principal consequences of dementia, it is reasonable to question the value of measuring dementia-free life expectancy independently of life expectancy without physical disability. There are several reasons for making such a distinction. First, there is the extent of the loss; senile dementia involves a rapid and global loss of function, and the services provided to physically disabled persons are often inappropriate. Elderly persons with senile dementia not only have difficulty in carrying out tasks but may attempt to perform tasks at inappropriate times. Admissions to long-term care thus tend to be related less to degree of functional loss than to problems of supervision.[7,8] In addition, persons with senile dementia are unable to appreciate the implications of their disorder or make decisions concerning their own care. Health services must therefore assume not only the physical care but also the decision-making functions of the person.

It is the aim of the present paper to provide a first estimation of life expectancy without irreversible progressive intellectual deterioration, or dementia-free life expectancy. The calculation is made for the French population in 1990. The data and methods of calculation used are described in sufficient detail to permit researchers in other countries to replicate the calculations where similar data is available.

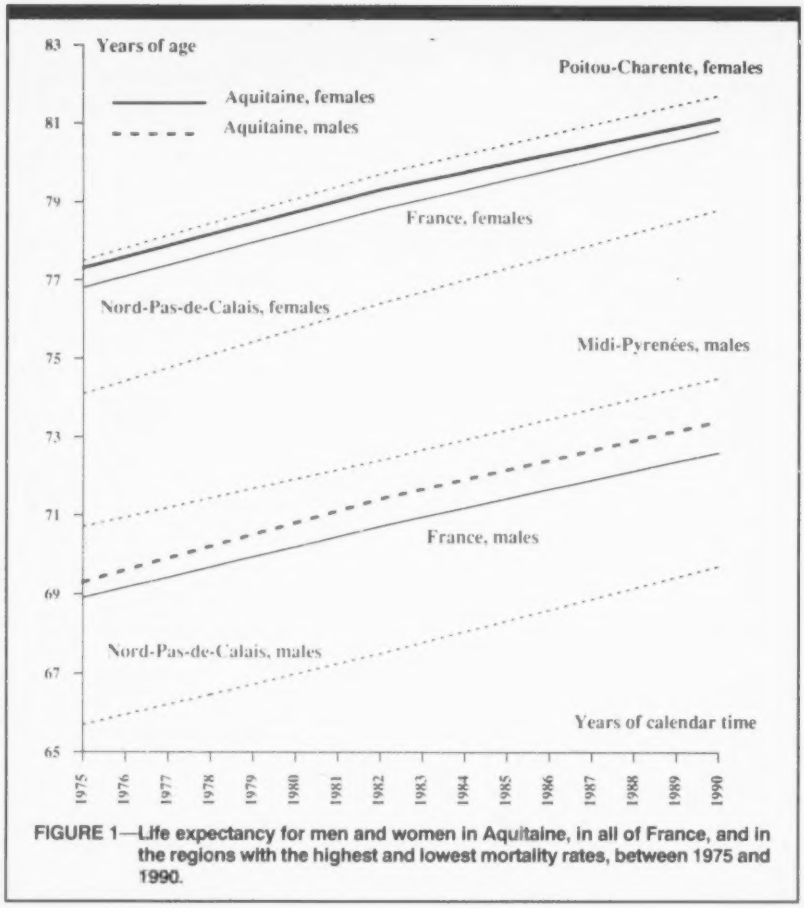

FIGURE 1—Life expectancy for men and women in Aquitaine, in all of France, and in the regions with the highest and lowest mortality rates, between 1975 and 1990.

Methods

Data Sources

Senile dementia prevalence data. Undoubtedly, the lack of interest in dementia-free life expectancy studies to date has been due largely to the difficulties inherent in the detection of senile dementia in the general population. These problems have been discussed in greater detail in relation to health expectancy studies in a previous communication.[9] The development of internationally recognized diagnostic criteria for senile dementia such as DSM-III-R[10] and ICD-9[11] have permitted epidemiologists since the 1980s to report relatively consistent prevalence rates for moderate to severe dementia of around 5% over age 65 across national boundaries.

There has, however, been considerable variation in the reported rates of mild dementia, which have ranged from 2.6% in Britain and Scandanavia[12] to 52.7% in Japan,[13] suggesting continued difficulty in the early recognition of the disorder. Epidemiological studies therefore tend at present to focus on moderate to severe dementia as the resultant prevalence estimates are more accurate and consistent than those for mild dementia. In a meta-analysis[4] of 13 general population studies conducted in Europe, the United States, Canada, and Asia, and employing internationally recognized diagnostic criteria of senile dementia, we were able to derive the following general logistic model of the relationship between age and prevalence:

$$\log_e(p) = -12.43(0.62) + 0.121(0.00785)\ \text{Age},$$

where $\log_e(p)$ represents the proportion of case. No significant differences were found among the 13 studies for either slopes or intercepts; studies using DSM-III-R criteria were found to provide the best fit.

The senile dementia prevalence data used for the present dementia-free life expectancy calculation come from a study of normal and pathological brain aging conducted in the Bordeaux region of France.[14] The project, known as PAQUID (Personnes Agées Quid), is a prospective study of a representative random sample from the electoral roli of 3777 persons older than 65 years living independently in two administrative departments of Aquitaine. The PAQUID study is supplemented by a random sample of 357 elderly persons living in institutions (the PAVIN [Personnes Agées Vivant en Institution] program). The institutionalized population is overrepresented, as the percentage of elderly persons living in institutions in the area is only 6%. A weighting system is therefore used in the calculation of prevalence rates to adjust for this overrepresentation. The samples are stratified by age, sex, and size of the community.

The diagnosis of dementia is made in two stages: systematic neuropsychometric screening of all subjects by a psychologist using DSM-III-R criteria, followed by confirmation of positive cases by a neurologist. The prevalence rates derived from this study show a good fit with the model derived from the meta-analysis, suggesting that the PAQUID–PAVIN data are consistent with rates reported

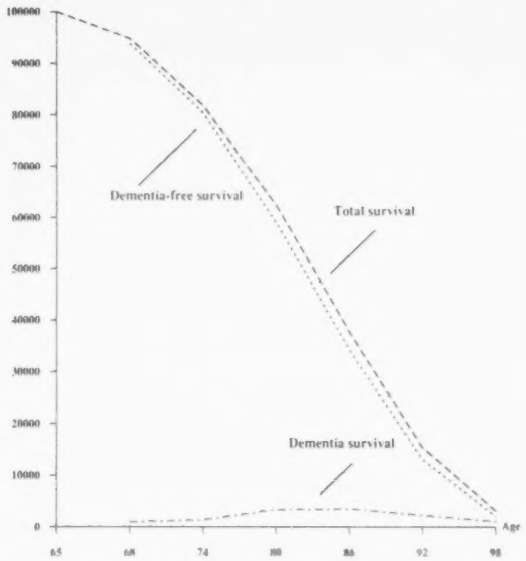

FIGURE 2—Proportion of dementia-free survivors and those with dementia, between the ages of 65 and 98 years, estimated for metropolitan France, 1988–1990 (both sexes combined).

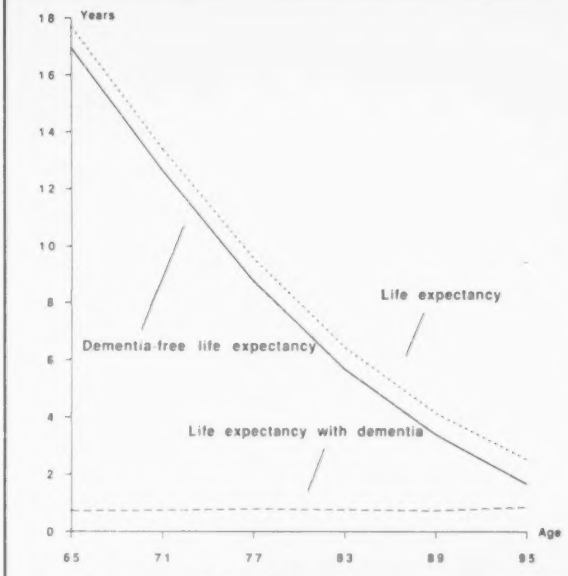

FIGURE 3—Dementia-free life expectancy for persons between the ages of 65 and 95 years, as calculated by Sullivan's method in comparison with total life expectancy and life expectancy with dementia, France, 1988–1990 (both sexes combined).

elsewhere. Although PAQUID and PAVIN are longitudinal studies, a complete data set is presently available only for the first year. These cross-sectional data were collected between January 1988 and October 1990. The prevalence estimates are for moderate to severe dementia; possible mild dementia has been excluded.

The observed percentage prevalence of senile dementia in Aquitaine is derived from the weighted combination of observations from PAQUID and PAVIN. The data were broken down by 6-year age groups because our previous meta-analysis indicated that senile dementia rates double every 6 years. The following prevalence rates were found (number of persons in each age group are given in parentheses for PAQUID/PAVIN): 1.06% between ages 65 and 70 years (953/35), 1.67% between ages 71 and 76 years (730/45), 5.41% between ages 77 and 82 years (659/77), 9.33% between ages 83 and 88 years (330/112), 15.01% between ages 89 and 94 years (97/71), and 34.13% between ages 95 and 100 years (11/16).

Mortality data. A life table for France for the years 1988 through 1990 for each year of age between 65 and 100 years for both sexes combined was provided by the National Institute for Statistics and Economic Studies.[15] After each census the Institute also publishes mortality data for each of the regions of France. Provisional life expectancies at birth are presently available for the years 1989 and 1990 combined[16,17]; from these data we were able to ascertain that life expectancy in the Aquitaine region is one of the highest in France, for both men and women. This is seen in Figure 1, which situates Aquitaine in relation to France as a whole and in relation to the regions with the lowest life expectancy (Nord-Pas-de-Calais) and the highest life expectancy (Poitou for women and Midi-Pyrenées for men).

If mortality rates remain stable, Aquitaine's current rates reflect the situation for the whole of France in about 3 years. For the purposes of this study, the Institute has also provided us with provisional mortality quotients for the Aquitaine region at 1-year intervals from 65 to 97 for both sexes combined calculated from the 1989 and 1990 data. Both national and regional mortality data are therefore combined with the regional senile dementia prevalence data. While it is desirable to combine mortality and morbidity data from the same region, the larger numbers obtained from the national estimates are likely to be less subject to sampling bias. We are also primarily interested in the calculation of national estimates. Mortality rates are summarized in a single figure, that of life expectancy at age 65 years (or mean duration of life after age 65 years). This is the mean of the ages at death of a fictitious generation of persons older than 65 years within the mortality conditions in France and Aquitaine.

Calculation Methods

Sullivan's method[18] has been chosen for the estimation of dementia-free life expectancy. It is the only method that permits the use of prevalence data in the calculation of health expectancies, a characteristic that accounts for the method's widespread use.[1] As a result of its popularity it is probably the method whose limits and biases are best understood. The principle behind Sullivan's method is very straightforward. From a period life table a calculation is made of the number of years lived between different ages by a fictitious cohort living all its life in the conditions of the period. Then the observed prevalence rates at each age or by age group are used to estimate the number of years lived with or without the specific morbid condition.

Results

For persons in metropolitan France aged 65 years between 1988 and 1990, life expectancy for both sexes combined is 17.7 years, giving a mean age at death of 82.7 years. The proportion of nondemented survivors after age 65 also decreases regularly in parallel with the number of survivors (see Figure 2). The

proportion of survivors is 75% at 76 years, 50% at 83 years, and 25% at 88 years; the proportion of nondemented survivors is estimated at 75% at 75 years, 50% at 82 years, and 25% at 87 years. There is thus a gap of just under a year for the entire length of the survival curve. The proportion of demented survivors in relation to the total number in the initial cohort increases from 1% at 68 years to reach a plateau of 3.5% at 80 through 86 years, then decreases steadily to 2.5% at 92 years and almost 1% at 98 years. This observation, illustrated in Figure 2, is due to a decrease with age due to mortality concurrent with the increase with age of the number of persons becoming demented. The maximum number of survivors in the population with dementia are found between the ages of 80 and 86 years (Figure 2); that is, the modal or largest number of persons with dementia are in their mid-80s. We might conclude from this that although the prevalence of dementia increases with age, when we adjust for mortality we see that the greatest burden in terms of health care provision will be for persons in their early 80s.

At 65 years dementia-free life expectancy is 16.9 years, within a total life expectancy of 17.7 years; at 77 years, dementia-free life expectancy is 8.7 years within a total life expectancy of 9.6 years; and at 89 years, it is 3.4 years within a total life expectancy of 4.2 years. As for the proportion of survivors, dementia-free life expectancy decreases regularly with age in parallel with the decrease in total life expectancy, with the rather curious result (see Figure 3) that life expectancy with dementia (not to be confused with average duration of survival of persons who become demented) does not vary with age after 65 years but stays constant at around 0.8 years. Between 65 and 95 years the survivors at each age have a continual expectation of living 0.8 years with dementia.

Life expectancy without dementia takes up 96% of life expectancy at 65 years, 91% at 77 years, and 81% at 89 years. At 95 years, life expectancy without dementia still represents only 67% of life expectancy, a figure that is probably artificially low owing to small numbers. This suggests that the proportion of life years spent in dementia grows with the number of years lived; however, the calculation of the regression line for each 6-year age group indicates that we would have to go beyond 170 years of age before dementia represented the totality of residual life expectancy. In other words, contrary to the fears commonly expressed by geriatricians, it is highly unlikely that all persons will be demented even at a very advanced age.

[a]As estimated by Sullivan's method.

Values of dementia-free life expectancy and dementia-free life expectancy as a proportion of life expectancy are given in Table 1 for ages 65 through 95 by 6-year age groups, for men and women and for both Aquitaine and France as a whole. As for disability-free life expectancy, it can be seen that at each age women have a higher dementia-free life expectancy. The results suggest that the gains in life years made by women will not be only years of dementia, nor will they be all years of good mental health; rather, women will experience the same mixture of good and poor mental health as men.

As noted above, current mortality conditions in Aquitaine appear to reflect the situation in France as a whole in about

3 years' time. If this is indeed the case then it may be predicted that there will be a future tendency in France toward an increase in dementia-free life expectancy at age 65, but that dementia-free life expectancy as a proportion of life expectancy will fall slightly (assuming dementia prevalence rates remain relatively stable).

Discussion

The calculation of dementia-free life expectancy represents a synthesis of progress made over the last 10 years in four fundamental areas of health science: (1) the elaboration of the concept of health to include quality of life and the impact of disease on society; (2) improvements in the diagnostic algorithms relating to dimensional chronic disabilities; (3) the development and validation of research instruments suitable for population research; and (4) the construction of synthetic indicators for the description of the global health status of populations.

From this study we are able to appreciate the global burden of senile dementia in Aquitaine in 1989/90, and probably for the whole of France in the coming years, given that dementia prevalence rates are not likely to differ significantly between Aquitaine and the rest of France. As the data provided by PAQUID and PAVIN closely resemble the general model of dementia prevalence derived from our previous meta-analysis of 13 recent studies, we can probably assume that the dementia-free life expectancy values found in this analysis will be approximately the same in other developed countries with similar mortality rates. The present analysis applies only to moderate and severe dementia. In public health terms, this is perhaps not too great a loss, as persons with mild dementia have only occasional difficulties that do not prevent them from living independently and the need for health service intervention for this group is negligible.

Conclusions

Like many other health expectancy studies, ours has of course been limited by the nature of the data available. As PAQUID and PAVIN are longitudinal studies, it will be possible in future years to calculate the computed period prevalence of dementia by which a fictitious cohort may be subject to the morbidity conditions occurring between consecutive rounds of the study (that is, incidence by age). As Brouard and Robine[19] have pointed out, this would provide a far more accurate estimation. The more recent calculation methods described in the literature have largely been developed to take into account the transience of disability and the multiplicity of outcomes possible. In the case of senile dementia this need is less pressing, as senile dementia is irreversible and no specific medical treatment is presently available. Furthermore, by directly combining disease prevalence with mortality, Sullivan's method implicitly takes into account the reversibility of health states.

As PAQUID and PAVIN also provide data on other aspects of health status (in particular activities of daily living and social support), future calculations may also provide estimates of life expectancy without social isolation and without loss of activities of daily living. Such estimates will permit the examination of their interrelationship with dementia-free life expectancy. Future calculations may also take possible etiological factors into account; for example, it may be possible to calculate dementia-free life expectancy for persons with different levels of education or with exposure to different risk factors. It is hoped that the present study will be used by other workers in the field of health evaluation to produce estimates of dementia-free life expectancy, thus providing a basis for international comparisons. □

Acknowledgments

The authors wish to thank Michel Isnard, INSEE, for providing them with recent and as yet unpublished mortality data for use in the calculations reported here.

The Prevalence and Demographics of Pathological Gamblers: Implications for Public Health

ABSTRACT

Objectives. A study of pathological gambling in five states provides information needed to address the public health threat that the expanding availability of legalized gambling poses to at-risk groups in the general population.

Methods. Over the course of this project, epidemiological data were collected to determine the prevalence of probable pathological gambling in the general population in each study state and demographic data were collected from pathological gamblers entering treatment programs in each state.

Results. Among the states surveyed, the availability of and involvement in gambling differ significantly, as does the prevalence of pathological gambling. Despite these differences, the demographics of pathological gamblers in these states are similar. Like those in the general population, pathological gamblers entering treatment in each state are similar. However, pathological gamblers entering treatment do not represent the full spectrum of individuals in the general population who experience gambling-related problems.

Conclusions. These findings raise a number of issues, including the potential impacts of continued gambling legalization on the overall rate of gambling problems in the general population and on specific at-risk groups, including women, minorities, and children. They thus have implications for policy and program decisions now being made throughout the United States. (*Am J Public Health.* 1994;84:237–241)

Rachel A. Volberg, PhD

Introduction

In the 1970s, as states experienced increasingly serious financial problems, state legislatures around the country began to legalize many types of gambling. Initially, states legalized lotteries with daily and weekly drawings and, later, instant scratch-off games. Beginning in the 1980s, states legalized pull-tab games and card rooms. Toward the end of the decade, increasing numbers of states legalized riverboats, low-stakes casinos, and video lottery terminals. With the passage of the federal Indian Gaming Regulatory Act in 1988, states around the country have seen the establishment of casino gambling on Native American lands. In 1991, Americans legally wagered $304 billion on all types of gambling, including parimutuels, lotteries, casinos, bookmaking, cards, bingo, and charitable gaming.[1]

The field of public health encompasses a myriad of environmental and behavioral threats to physical and mental health. In addressing such threats, the development of effective preventive, therapeutic, and rehabilitative interventions requires the accurate identification of the risks associated with these threats.[3,4] The proliferation of legalized gambling in the United States constitutes a public health issue because of the adverse effects that new forms of gambling can have on overall prevalence rates as well as on at-risk groups in the general population. At one end of a continuum of problematic gambling involvement is pathological gambling, characterized by a loss of control over gambling, the chasing of losses, lies and deception, family and job disruption, financial bailouts, and illegal acts.[2] In spite of recent increases in public awareness of pathological gambling as a treatable disorder and the increased availability of treatment services for individuals with gambling-related problems, this issue has yet to be conceptualized in meaningful public health terms.

Until recently, little empirical data have been available to address these issues. However, a recently completed study of the prevalence and treatment of pathological gambling in five states provides a foundation on which to begin addressing essential public health issues related to the expanding availability of legalized gambling. During this project, prevalence surveys of gambling involvement and pathological gambling were carried out in each state. In addition, information was collected on the demographic characteristics of clients in each state's gambling treatment programs. The results of those prevalence surveys are outlined below, the demographics of pathological gamblers in the general population and in treatment are reviewed, and the public health implications of these data are addressed.

Methods

Two major types of data were collected over the course of this project: (1) epidemiological data to determine the prevalence of probable pathological gambling in the general population in each study state, and (2) demographic data from pathological gamblers entering treatment programs in each state.

Prevalence Surveys

Like an earlier survey conducted in New York, the surveys funded by the Na-

TABLE 1—Gambling Involvement and Prevalence of Pathological Gambling in the General Population

State	Lifetime Gambling Participation, % (n = 4500)	Mean No. of Gambling Activities (n = 4500)	Prevalence Rate, % (n = 4500)	1987 Per Capita Lottery Sales, $[a]
Massachusetts	90	3.51	2.3	216
Maryland	89	3.66	1.5	168
New Jersey	92	4.05	1.4	146
California	89	3.86	1.2	50
Iowa	84	3.05	0.1	35

[a]Adapted from Clotfelter and Cook.[18]

tional Institute of Mental Health were based on the South Oaks Gambling Screen (SOGS),[5,6] a 20-item scale derived from the psychiatric criteria for pathological gambling.[2] In developing the SOGS, a large pool of variables was subjected to discriminant analysis, the results of which were cross-tabulated with assessments of independent counselors. This instrument has been found valid and reliable in distinguishing probable pathological gamblers among hospital workers, university students, high school students, prison inmates, and inpatients in alcohol and substance abuse treatment programs.[7-9] The term "probable" is used to distinguish between this method of assessment and a diagnosis based on clinical evaluation.

The questionnaire for the surveys assessed respondents' (1) experience with 10 types of gambling (lotteries, casino table games, gaming machines, bingo, card games, dice games, parimutuel wagering, stockmarket activities, games of skill, and sports), (2) gambling-related problems, and (3) demographic characteristics. The surveys were carried out by telephone between April 1988 and April 1990. The number of interviews completed in each state was determined by balancing available resources, confidence intervals, and the size of each state's population. In California, 1250 interviews were completed; 1000 interviews were completed in New Jersey; and 750 were completed in Maryland, Massachusetts, and Iowa.

The sampling design in all the surveys was constructed to ensure that inferences could be drawn between the samples and the population aged 18 and over in these states. The samples from each state were stratified to proportionally represent county populations on the basis of 1980 census figures. Random-digit dialing and random selection of respondents within households were used. The refusal rate was 24% in Iowa, 27% in California, 31% in Massachusetts, 34% in Maryland, and 36% in New Jersey.

Client Demographics

In developing this project, one of the criteria used for selecting the study states was whether these states provided public funding for the treatment of pathological gambling. In 1987, New Jersey operated three outpatient treatment programs, Iowa provided outpatient services at 11 existing alcohol and substance abuse treatment centers, Maryland provided services at a psychiatric hospital and three associated community treatment programs, and Massachusetts had two hospital-based outpatient programs for pathological gamblers. California did not have treatment services for pathological gamblers but was included because of pending legislation to establish funding for such services. This legislation was subsequently defeated.

Treatment programs in all the study states based their diagnosis of pathological gambling on the psychiatric criteria that were also used in developing the SOGS.[2] Aggregate data for all clients entering publicly funded treatment programs in New Jersey and Iowa were provided by the New Jersey Division of Alcoholism and by the Iowa Department of Human Services.[10,11] In Maryland, demographic data were abstracted from client records by staff of the psychiatric hospital overseeing treatment for the state's pathological gamblers.[12] The Harvard Center for Addiction Studies provided demographic data on all clients entering treatment in Massachusetts.[13] In California, demographic data on pathological gamblers in treatment were abstracted by the author from the case records of clients treated by private practitioners. Comparison of these data with demographic information from Gamblers Anonymous[14,15] and from treatment programs in other states[16,17] indicate that the pathological gamblers entering treatment in this study are representative of pathological gamblers entering self-help and professional treatment programs throughout the United States.

Results

The study states differ in gambling involvement and in pathological gambling prevalence rates. Individuals entering treatment for gambling-related problems, as well as those in the general population, differ in gambling involvement and demographic characteristics.

Gambling Availability, Involvement, and Prevalence of Pathological Gambling

Lotteries in Massachusetts, Maryland, and New Jersey were started between 1971 and 1973 while lotteries in California and Iowa were started in 1985. Casinos were legalized in New Jersey in 1976 but have been available to California residents since the 1930s. Horse and dog racing have been available for at least 30 years in all the states, and off-track wagering has been available in the East Coast states and in California for nearly 20 years. Charitable gaming such as bingo is widely available in all the study states.

Table 1 shows differences in lifetime participation in gambling and in mean number of lifetime gambling activities for all respondents across the study states. Lifetime participation and mean number of gambling activities are highest in New Jersey and lowest in Iowa. Differences between Iowa and the other study states in these measures are statistically significant ($P < .01$, as determined by chi-square analysis). In addition, per capita lottery sales are highest in Massachusetts and lowest in Iowa.

Per capita wagering, apart from lottery sales, is difficult to correlate with prevalence rates of pathological gambling. One reason is that information on per capita wagering is not easily available on a state-by-state basis. Additionally, differences in gambling expenditures may be the result of educational and income differences that affect participation in gambling, of sociocultural differences that lead to differential participation in many types of gambling, and of the increasingly regional nature of many types of gambling.

Consistent with prior uses of the SOGS,[5,6,19] respondents in the general population surveys scoring 5 or more points were classified as "probable pathological gamblers." The prevalence rate of

probable pathological gambling in each state is also shown in Table 1.

One striking difference that emerges from these data is that the prevalence rate of probable pathological gambling in the Eastern states and California is significantly higher than that in Iowa ($P < .01$, as determined by chi-square analysis). As noted above, legalized gambling, particularly state lotteries and casinos, has been available to the residents of the East Coast states and California for many more years than it has been in the Midwest. Gambling participation and per capita lottery sales are also significantly higher in the East Coast states and California than in Iowa.

Comparing Pathological Gamblers in the General Population and in Treatment

There are significant differences, again as determined by chi-square analysis, between the overall survey sample and those respondents who scored as probable pathological gamblers along several demographic dimensions. However, the only significant difference between probable pathological gamblers from different states is that those from the East Coast states and California are significantly more likely to be non-White than those from Iowa.

Differences between the overall sample and those respondents who scored as probable pathological gamblers are detailed in Table 2. As this table makes clear, probable pathological gamblers are significantly more likely than the general population to be male and non-White, to have lower education, and to be unmarried. Probable pathological gamblers also differ from the general population in their lifetime participation in many types of gambling, particularly wagering on cards, horse and dog races, games of skill, dice games, and sports, as well as in the frequency of their wagering. Involvement in gambling was not a basis for categorizing respondents as probable pathological gamblers.

Like the characteristics of probable pathological gamblers in the general population, those of pathological gamblers entering treatment in New Jersey, Maryland, Massachusetts, Iowa, and California are strikingly homogeneous. Table 2 shows the demographic profile of pathological gamblers entering professional treatment programs in each study state as well as of those in the general population.

As this table shows, the great majority of pathological gamblers entering treatment are White, middle-aged men. By contrast, those scoring as probable pathological gamblers in the general population are more likely to be women and minorities, as well as less likely to have graduated from high school than pathological gamblers entering treatment in every state. Additionally, they are less likely to be married than those entering treatment in every state except California. It is worth noting that none of the probable pathological gamblers in the general population had ever sought treatment for a gambling problem.

TABLE 2—Characteristics of Pathological Gamblers in Professional Treatment Programs and in the General Population

	Total Survey Sample (n = 4442)	Probable Pathological Gamblers in Survey Sample (n = 58)	New Jersey (n = 155)	Maryland (n = 276)	Massachusetts (n = 137)	Iowa (n = 135)	California (n = 71)
Male, %	43	76*	93	91	93	86	93

*Statistically significant difference between overall sample and probable pathological gamblers ($P < .01$) tested by chi-square analysis.

Discussion

These findings have implications for policy and program decisions now being made throughout the United States. The data raise a number of issues, including the potential impacts of continued gambling legalization on the overall rate of gambling problems in the general population and on specific at-risk groups, including women, minorities, and children.

Gambling Legalization and Prevalence Rates

In states where legal gambling has been available for less than 10 years, less than 0.5% of the adult population were classified as probable pathological gamblers. In states where legal gambling has been available for more than 20 years, approximately 1.5% of the adult population were classified as probable pathological gamblers. Together, these data support the long-standing contention of treatment professionals and researchers that increasing the availability of gambling will contribute to an increase in the prevalence of gambling-related problems in the general population.[20,21]

Research from Australia and Canada[22,23] suggests that weekly gambling and regular heavy losses are correlated with the development of gambling-related problems. We have shown that there are significant differences in lifetime gambling participation, mean numbers of gambling activities, and per capita lottery sales across the study states. While the relationship between gambling involvement, gambling expenditures, and pathological gambling across these states is not completely linear, the strong association between these variables deserves continued investigation.

Because the availability of many types of gambling is expected to increase throughout the 1990s, the public health issue is to find ways to minimize the harm that some groups will experience in relation to the expansion of gambling. Increased and reliable funding for prevention, treatment, and rehabilitation of pathological gamblers is an important first step. State legislatures may want to consider additional measures, such as establishing hotline and crisis intervention services; training mental health and substance abuse treatment professionals to recognize and address gambling-related problems among their clients; training criminal justice and prison officials to recognize the illegal activities and suicidal tendencies of some pathological gamblers; and funding research on gambling and gambling-related problems among women, minorities, and youth.

Gambling and Women

While pathological gambling affects men more often than it does women, female pathological gamblers are much less likely to enter treatment for a gambling-related problem. This is analogous to the treatment of alcoholism, in which the stigma of being a female alcoholic was

once so great that women were unlikely to seek treatment and, if they did, likely to be misdiagnosed.[24] To reach women experiencing problems related to their gambling, it will be important to focus public education and outreach efforts on venues where women are more likely to gamble, such as lottery retail outlets and bingo halls. It will also be essential to train mental health and substance abuse treatment professionals to recognize gambling problems among their women clients.

Gambling and Minorities

The data presented here show that ethnic minorities are seriously underrepresented among pathological gamblers entering treatment. An especially important issue in this regard is the potential impact of increased legal gambling on Native Americans. The Indian Gaming Regulatory Act of 1988 has led to the establishment of casino gambling on numerous reservations throughout the United States. Given the history and experience of Native Americans with alcoholism,[25–27] we must wonder whether gambling will prove equally devastating.

Preliminary information on gambling involvement and gambling-related problems among Native Americans in one state[28] shows that the prevalence rate of probable pathological gambling is significantly higher in this specific population than it is in the general population of the same state. Native American tribal governments as well as the Indian Health Service will want to develop initiatives to address the issue of pathological gambling on reservations, particularly in those states where compacts permitting casino gambling have been established.

Gambling and Youth

In Iowa and Massachusetts, we added to the survey instrument several questions that were intended to improve our understanding of how gambling problems develop. The questions focused on the respondents' age and preferred types of gambling at different points in time. Analysis shows that 8% of the Iowa respondents and 7% of the Massachusetts respondents who gambled began wagering before the age of 15. In contrast, 23% of the problem and pathological gamblers in Iowa and 36% of such gamblers in Massachusetts began wagering before the age of 15.

These data confirm clinical evidence that extensive childhood involvement in gambling is predictive of later gambling problems. Access to gaming venues by young people is difficult to control, as evidenced by the numbers of high school students and underage college students who gamble in casinos, buy lottery tickets, and place bets on horse and dog races.[18,29,30] Regulating access to new gaming venues by children and teenagers may be a critical factor in minimizing the prevalence of gambling-related problems in later life. It will also be important to increase awareness of the risks of early gambling involvement among teachers, parents, and children themselves.

Conclusion

Until well into the 20th century, excessive gambling losses were regarded as an individual failing rather than as a social or public health problem. However, data from surveys of gambling involvement in the general population and from treatment programs for pathological gambling raise serious public health concerns in relation to the proliferation of legalized gambling. As legalized gambling spreads, pressures will increase on the gaming industries, state governments, and mental health and substance abuse treatment professionals to develop effective responses to problems related to the expanding availability of gambling.

Researchers, treatment professionals, gaming industry representatives, and policymakers must work together to address these issues and to develop innovative approaches for helping individuals who experience severe problems when they gamble. It is incumbent on all these parties to consider how best to prevent the probable increases in pathological gambling that loom in the future and to ensure that services are available to those individuals whose lives are disrupted by gambling. □

WFPHA International Congress on Health, Economics, and Development

The World Federation of Public Health Associations (WFPHA) will hold its Seventh International Congress, "Health, Economics, and Development: Working Together for Change," December 5 through 8, 1994, in Bali, Indonesia. [Note revised date for conference.] Join health practitioners, policymakers, administrators, development workers, economists, researchers, and many others from governments, international organizations, and private groups in this exciting and ambitious event. Examine the linkages among health, economics, and development. Develop an action agenda to integrate health concerns with economic and development policies.

The WFPHA is a nongovernmental organization composed of national public health associations from 41 countries around the world. WFPHA congresses are held every 3 years and are cosponsored by the World Health Organization and the United Nations Children's Fund. This congress will be hosted by the Indonesian Public Health Association. Participation is open to all. The official language of the congress is English.

For further information and abstract forms, contact WFPHA Secretariat, c/o American Public Health Association, 1015 15th St NW, Suite 300, Washington, DC 20005 USA; fax (202) 789-5681. The deadline for abstract submission is *May 15, 1994*.

Sedatives and Hypnotics in Stockholm: Social Factors and Kinds of Use

Göran Blennow, MD, Anders Romelsjö, MD, PhD, Håkan Leifman, BA, Anders Leifman, MSD, and Gunilla Karlsson, MD

ABSTRACT

Objectives. The aims of the study were (1) to estimate prevalence rates of current, regular, and long-term use of sedatives and hypnotics and the incidence of regular use in an urban population and (2) to study the association between such use of drugs and sociodemographic factors, symptoms of disease, and alcohol consumption.

Methods. Data on drug use in a random sample of 6217 adults in Stockholm County were analyzed with logistic regression.

Results. The prevalence rate for current use of sedatives or hypnotics was 12.8% among men and 18.6% among women; the rate for regular use was 3.7% among males and 4.7% among females. The odds ratio for current use increased with age and was higher among unemployed persons and disability pensioners, high consumers of alcohol, persons with an increased level of symptoms, and widows. More than 25% of the persons who had used sedatives or hypnotics during the previous 2 weeks were regular users 6 months later. For persons aged 25 through 64 years, the annual incidence rate was 1.8% among men and 2.7% among women.

Conclusions. The comparatively low incidence and high prevalence of regular use implies that long-term use of sedatives and hypnotics is common. (*Am J Public Health.* 1994;84: 242–246)

Introduction

The use of sedative and hypnotic drugs has increased in Europe since World War II and peaked in the early 1970s.[1] In Sweden and elsewhere, benzodiazepines are the most frequently used drugs,[2] at least in part because of their beneficial clinical effects and low toxicity.[1-3] In a 1981 study including the United States and 10 Western European countries, Balter found a prevalence rate of 8.6% in Sweden for use of sedative drugs, once or repeatedly; the prevalence rate for the United States was estimated at 12.9%.[4] However, several reports have stressed a risk of dependence in long-term benzodiazepine maintenance.[5-7]

Studies on the use of sedative and hypnotic drugs have revealed higher than average prevalence rates among divorced, separated, or widowed persons and elderly persons,[8-10] and low rates among the best educated.[11] It has also been shown that concomitant use of alcohol and sedatives or hypnotics is common.[12,13] Thus, there seem to be associations between social factors, alcohol use, and use of sedatives and hypnotics. However, it is not known whether there are any differences in these associations between current and regular users. This is an important issue in an analysis of the risk of dependence, and it carries implications about the question of proper vs unnecessary use.

In the present study we considered the following questions:

1. What is the prevalence of current use, regular use, and long-term use, and what is the incidence of regular use?
2. Is the social pattern and the connection to alcohol consumption different for current users and regular users?

Methods

The Health of the Population Study[14] was a cross-sectional health survey of random samples of 450 inhabitants aged 18 years and older in each of the catchment areas of 14 primary care teams at four primary health care districts in Stockholm County, which has a total of 1.5 million inhabitants. The proportion of blue-collar workers in the population in the study area was 36%; the proportion of subjects aged 65 years and older was 16%; and the proportion of unmarried persons was 37%. For Stockholm County as a whole, these proportions were 32%, 19%, and 33%, respectively.[15] Our analyses are based on a net sample of 6217 subjects (with due corrections for deaths, moves, etc.). A total of 4094 subjects (65.9%) responded to a mail questionnaire followed by up to three reminders, in April through June 1984. The second reminder to main immigrant groups included a questionnaire translated into their respective native tongues. A health examination (directed to the whole sample group) was conducted between September 1984 and March 1985 by district nurses and nurses' assistants specially trained for the purpose. The average time between the investigators' receipt of the completed questionnaire and the health examination was about 6 months

(mean time, 172 days; range, 116–228 days). Altogether, 3801 subjects (61.4%) attended the health examination; 2652 subjects aged 18 through 64 years participated in both the questionnaire study and the health examination.

Use of Sedatives and Hypnotics

The questionnaire contained questions about use during the previous 2 weeks of "drugs . . . for daytime use (i.e., Librium, Valium, Stesolid, Apozepam, and Sobril)" (sedatives) and "drugs . . . for nighttime use" (hypnotics). The reply alternatives were "No," "Yes, occasionally," "Yes, daily or almost daily," and "Do not know." In the health examination, subjects aged 18 through 64 years were asked about sedatives or hypnotics they had used at least 3 days a week during the previous 3 months. Since the name of the drug was stated, a separate group of benzodiazepine users could be created. The questionnaire data thus allowed us to estimate prevalence rates of current use, while the health examination formed the basis for the estimation of regular use of sedatives and hypnotics—and, separately, benzodiazepines—among persons aged 18 through 64 years. The prevalence rate of long-term use, that is, use of sedatives or hypnotics indicated in both investigations, was also calculated, as well as the incidence rate (the rate for those who stated that they used sedative or hypnotic drugs at the health examination but who did not report such use in the questionnaire).

Socioeconomic Status

Socioeconomic status was analyzed for all persons younger than 65 years, which is the retirement age in Sweden. The unemployed formed one category and the disability pensioners formed another. The remaining persons (approximately 90%) who stated an occupation were classified into various groups according to the Swedish socioeconomic classification system used in censuses as a measure of social class; the system is based on the type and extent of education generally needed for various occupations.[16] In the statistical analyses, the blue-collar workers were chosen as the reference category.

Marital Status

The marital status categories were unmarried (never married), married (reference group), divorced, and widowed.

Measures of Alcohol Consumption

The reported customary consumption of liquor, fortified wine, table wine, strong beer (5.5% alcohol by volume) and ordinary beer (3.5% alcohol by volume) was converted to grams 100% ethanol, using data on the average content of the various alcoholic beverages in 1984 (Göran Christensen, the Alcohol Retail Monopoly, personal communication, February 1984). The cut-off point for high consumption was 35 g per day for men and 25 g for women, consistent with recent recommendations.[17–19]

Symptoms

A dichotomized measure was constructed from the answers to questions about frequency of symptoms ("Never," "Seldom," "Sometimes," "Often," scored 1, 2, 3, and 4, respectively) covering 22 somatic, psychological, or psychosomatic entities. These symptoms were difficulty in sleeping, difficulty in falling asleep, poor appetite, heartburn, diarrhea, constipation, epigastralgia, flatulence, headache, palpitations, breathing problems, vertigo, depression, restlessness, anxiety, tiredness, indolence, muscle tension, breast pain, arthralgia, coughing, and incontinence. The measure for the 20% of subjects with the highest score (43–76) was coded as 1, and the measure for the others was coded as 0.

Analyses

The prevalence rates for current and regular use of sedatives and hypnotics were calculated first. Then multivariate logistic regression analyses were conducted for subjects aged 25 through 64 years for whom information about these two measures was available. The age category 25 through 44 years was used as the reference category. (Because there were few subjects aged 18 through 24 years, some of whom were not employed, this age group was excluded from the multivariate analyses.) The odds ratio, with 95% confidence intervals, was used as a measure of relative risk.[20]

Results

Current Use

Use of sedatives, hypnotics, or both during the previous 2 weeks was more common among women than men (the overall rate was 16%), increased with age, and was similar in all socioeconomic groups. The prevalence rates were lower for sedative use than for the use of hypnotics (Table 1). Drug use was most common among subjects in the following categories: disability pensioners of both sexes, unemployed women, self-employed men, and divorced or widowed persons. Prevalence rates were generally low among white-collar employees at medium and high levels. Subjects with a high level of symptoms had markedly higher prevalence rates than did those with few symptoms; high consumers of alcohol more frequently reported use of drugs than did others. Only three men and seven women aged 18 through 24 years had used sedative or hypnotic drugs during the previous 2 weeks, and only three subjects in this age group were regular users.

Regular Use

The prevalence rates for use of sedatives or hypnotics at least 3 days a week for a period of at least 3 months were about 25% as high as the rates for use during the 2 weeks before the subject answered the questionnaire (Tables 1 and 2). About 75% of the regular users took benzodiazepines. The socioeconomic distribution was generally similar for regular use and for current use, with the exception of self-employed men and unmarried persons; both categories had lower rates of regular use. There were no users among widowed men and few among self-employed men; however, there were few subjects in these categories.

The average weekly alcohol consumption among current sedative or hypnotic drug users aged 25 through 64 years was 200 g of 100% alcohol for men and 72 g for women, compared with 109 g and 49 g, respectively, among nonusers.

Long-Term Use

The prevalence rate of long-term use (6 months or more) of sedatives or hypnotics among current users aged 25 through 64 years was 26% (24 of 92) for men and 28% (44 of 156) for women. If only benzodiazepines were considered, the proportions were 16% and 18%, respectively. Of the regular users, 32 men (75%) and 44 women (76%) were long-term users. Of those who responded to the questionnaire, 2.6% of the men and 4.0% of the women admitted long-term use. The socioeconomic pattern of long-term use was similar to the pattern of both current and regular use. The annual incidence rate of regular use was 1.8% for men and 2.7% for women.

Multivariate Logistic Regression Analyses

Table 3 shows clear associations between certain social factors and use of sedatives or hypnotics; in some instances,

Note. Data are for subjects aged 18 through 64 years.

these associations are statistically significant. For current use among men, the odds ratios were significantly increased among the unemployed, disability pensioners, the self-employed, high alcohol consumers, and those with various symptoms. For current use among women, the odds ratios were significantly increased among those aged 45 through 54 years, low-level white-collar employees, widows, high consumers of alcohol, and those with various symptoms. In separate analyses of current users (excluding persons who were also regular users), a similar pattern was found. The most pronounced difference was the markedly increased odds ratio (4.41) for men with high alcohol consumption (95% confidence interval = 2.28, 8.55).

Men who were unemployed, disability pensioners, unmarried, or divorced or who showed symptoms had statistically significantly increased odds ratios for regular use of sedatives and hypnotics (Table 3). Among women, the odds ratios were statistically significantly increased for those aged 55 through 64 years and for those with symptoms. Thus we found both similarities and differences by gender, as well as differences in the sociodemographic pattern for regular use compared with current use. For men, odds ratios for being unmarried or divorced were statistically significantly increased only for regular use, and odds ratios for high alcohol consumption were increased only for current use. For women, the odds ratios were not increased for those who were unmarried or divorced with current or regular use of sedatives or hypnotics.

Discussion

The prevalence rate of current use of sedatives or hypnotics was 12.8% for men and 18.6% for women; these rates are higher than those found in some other surveys, including one from Sweden.[21] One interview survey of a random sample of the population indicated a prevalence rate of 3.6% for use of sedatives and 5% for hypnotics "occasionally or more frequently" during a previous 14-day period in Stockholm County in 1988[22]; another interview survey found a prevalence rate of 5.6% for use of sedatives and 5.4% for hypnotics.[21] Both surveys had an upper age limit of 74 years. If we apply this upper age limit to the Health of the Population Study sample, the prevalence rate of sedative use is reduced to 6.7% (5.4% for men and 7.7% for women) and that of hypnotic use is reduced to 11.2% (9.7% for men and

13% for women), and the prevalence rates are 11.7% for men and 15.8% for women for use of either type of drug. The higher prevalence rates of current use, especially of hypnotics, among those who responded to the questionnaire could be due partly to a reduced reluctance to admit such use in a questionnaire compared with a personal interview. It has been claimed that sensitive items usually attain a higher prevalence rate in questionnaires than in interviews.[23] It is therefore possible that underreporting contributed to a reduction of the prevalence rates found at the health examination. Another explanation could be that the use of sedatives and hypnotics actually was higher in the investigated areas in Stockholm County than in other areas.

We lack information about the use of sedatives and hypnotics among persons who did not participate in the study. However, because the prevalence in the Health of the Population Study sample for inpatient care with a diagnosis of alcoholism was two to three times higher among the nonparticipants than among the participants,[19] and because we demonstrated an association between high alcohol consumption and current use of sedatives or hypnotics in the present study, we believe that the prevalence of such use is also higher among the nonparticipants.

The increase in prevalence of use with age is in agreement with observations made by others.[24–27] When approximately 20% of persons aged 75 years and older use sedatives and approximately 40% use hypnotics, it is questionable whether appropriate indications are always present. Results of other studies indicate that use of sedatives and hypnotics implies an increased risk for falls and other accidents.[28]

A considerable variation in use of sedatives and hypnotics with socioeconomic status[13] and education[29] has been reported. We found a greatly increased prevalence of use among disability pensioners and unemployed persons of both sexes (Table 3). Being unemployed or on a disability pension is sometimes not just a short-term problem; it may have a long-term impact, especially on disability pensioners, who may feel they will never again take part in the working life. It is reasonable to believe that being unemployed or on a disability pension may be associated with a number of psychological problems caused by, for instance, social isolation. However, drug use in itself may be the reason for unemployment or a disability pension. There were increased odds ratios for current use among female low-level white-collar employees, who constitute the second largest category of gainfully employed women. One possible partial explanation is that a considerable number of women with limited work experience outside the home entered the work force; some may have received inappropriate, monotonous, or stressful jobs, developed (psychosomatic) symptoms, and subsequently been prescribed sedatives or hypnotics by physicians. We found increased odds ratios for regular use among divorced and unmarried men and for current use among widows, findings that have been reported elsewhere.[29] Other studies have shown that divorced persons have higher levels of psychic distress.[7,29] Widowed persons are more likely to suffer from depression.[30] These factors may contribute to increased odds ratios, but they do not explain the sex differences.

With symptoms	7.30 (4.76, 11.18)	4.72 (3.37, 6.62)	5.97 (2.57, 13.86)	7.56 (3.59, 15.94)

Note. Data are from a multiple logistic regression analysis of data for subjects aged 25 through 64 years; the age group 25 through 44 years served as the reference category. OR = odds ratio; CI = confidence interval.
[a]Use during the previous 2 weeks.
[b]Use at least 3 days a week for at least 3 months.

The markedly increased odds ratio for current, but not regular, use of sedatives or hypnotics in subjects of both sexes with high alcohol consumption may indicate that some high consumers occasionally use these drugs as an alternative to alcohol to achieve relaxation and sleep, maybe as a consequence of heavy drinking.

The distinction between current and regular use is somewhat arbitrary. No information is available on use prior to the period covered by the questionnaire or in between the two measurement points. It may very well be that some of the current users also used sedatives or hypnotics regularly or in periods preceding the presentation of the questionnaire.

The prevalence rate of regular use (at least 3 days per week during the previous 3 months), 3.7% in men and 4.7% in women, is about one-fourth the rate of current use. At the health examination about 6 months after the questionnaire was administered, 27% of the current users were still using the drugs, that is, were long-term users. Our measure of regular use is a clear indication of long-term use, inasmuch as 75% of the regular users were long-term users. In a prospective study in Jämtland County, 15% of the persons who were prescribed benzodiazepines for the first time in 1976 were regular users 10 years later (G. Boethius, MD, oral communication, October 1989), and 1.6% of men and 2.9% of women were regular users of psychoactive drugs in an analysis of four random samples of the Swedish population from 1975 to 1981.[31] As the follow-up period was longer in the former study and the latter excluded hypnotics, the present results seem to be roughly in concordance with the results of these two studies and with those of studies from other countries in which investigators

found that 10% to 18% of benzodiazepine users continued their use for 4 months or more.[32,33]

The annual incidence rates of regular use (1.8% for men and 2.7% for women) might be considered fairly modest. The much higher prevalence rates constitute an important indication that many people use these drugs for long periods of time, contrary to recommendations.[3] It should be kept in mind in this context that the incidence rates are based on a limited number of new cases and consequently have a low degree of precision.

The multivariate analyses showed that some of the independent factors related to current use were the same for both regular and long-term users, a finding that increases the credibility of the results.

The marked association between a high level of symptoms and current and regular use of sedatives or hypnotics among persons of both sexes in the working age groups is in agreement with the findings of other studies[8,14,29] and may be regarded as a reflection of a rational use of these drugs. Conversely, it might be argued that the high proportion of users with symptoms indicates insufficient effects of the sedative and hypnotic drugs. Some persons in this category should probably receive other treatment in addition to or instead of sedatives or hypnotics, and others might do as well or better without sedatives and hypnotics. It is regrettable that we do not know what proportion of users did not actually improve, got worse, or did not change after they started to use sedative and hypnotic drugs. This information is a prerequisite for a judgment of the extent of improper use.

Since there are hardly any documented therapeutic long-term effects of benzodiazepines[34]—the dominant subgroup of sedatives and hypnotics whose use can lead to dependence—and with the well-established risk of dependence in long-term use, the proportion of 27% long-term users among current users in this study is an alarmingly high figure. It indicates that a substantial minority of current "temporary" users continue to use sedatives or hypnotics for longer periods than are suitable for effective sedative or hypnotic results. Certain general principles for prescribing sedatives and hypnotics[35] can be suggested: (1) Use nonpharmacological means of promoting sleep whenever possible and reassure patients that 5 to 6 hours' sleep per night is normal. (2) Avoid prescribing benzodiazepines—especially for the elderly—and try to withdraw benzodiazepines as soon as possible. (3) As a general rule, prescribe sedatives and hypnotics only for short periods. (4) Warn patients of the risk of dependence.

The physician should also consider the important social factors associated with use of sedatives and hypnotics—apart from age and symptoms—and should be aware that temporary use of such drugs may be an indicator of at least transitory high alcohol consumption. □
